The exact amount of  $\text{Li}^+/\text{Na}^+$  ratios in  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals is important for working out the effect of substitution on the properties of materials. Atomic absorption spectroscopy (AAS) is used to determine the amount of  $\text{Li}^+$  doped in the  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals (molar fraction  $y$ ) and are compared with the molar fraction of  $\text{Li}^+$  in initial solution ( $x$ ). Table S1 shows the ideal molar fraction of  $\text{Li}^+$  in initial solution and the exact molar fraction of  $\text{Li}^+$  (*i. e.* the actual fraction of  $\text{Li}^+$ ) in the obtained  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals, respectively. Fig. S1 also gives the molar fraction of  $\text{Li}^+$  ions in the  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals depending on the molar fraction of  $\text{Li}^+$  in the initial solution, in which, the dashed line represents the ideal molar fraction of  $\text{Li}^+$  in initial solution and the solid line represents the actual molar fraction of  $\text{Li}^+$  in the obtained  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals. It can be seen that when the molar fraction of  $\text{Li}^+$  in the initial solution is less than 0.4, the fraction of  $\text{Li}^+$  in the obtained  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals is much lower than its ideal one in the initial solution, whereas the fraction of  $\text{Li}^+$  in the obtained  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals is slight higher than that one in the initial solution when  $x \geq 0.6$ . Most importantly, the fraction of  $\text{Li}^+$  in obtained  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals is almost same to that one in the initial solution when  $x = 0.5$ . The detailed explanations are given in the section of Supporting Information. This change trend may be explained through the principle of hard and soft acids and bases (HSAB) and solubility product rule as follows. According to HSAB, hard acids prefer to coordinate to hard bases and soft acids prefer to coordinate to soft bases [1, 2], where hard acids are defined as the acceptor atoms with high positive charge, small size and no easily polarized outer electrons, whereas hard

bases are the donor atom hardly oxidized with high electronegativity, low polarizability and only high energy empty orbitals. In aqueous solution,  $\text{H}_2\text{O}$  and  $[\text{ReF}_4]^-$  can be regarded as a Lewis base. Since  $[\text{ReF}_4]^-$  ( $\text{Re} = \text{Gd}, \text{Y}$ ) has a larger volume than  $\text{H}_2\text{O}$  molecule and has a negative charge, it is a softer base than  $\text{H}_2\text{O}$ . As a Lewis acid,  $\text{Li}^+$  has much larger ion potential than that of  $\text{Na}^+$ , hence its hardness is greater than that of  $\text{Na}^+$ . Therefore,  $\text{Li}^+$  tends to bond to  $\text{H}_2\text{O}$  to form a hydrated ion instead of forming  $\text{LiReF}_4$  precipitate with  $[\text{ReF}_4]^-$ , resulting in a larger solubility of  $\text{LiReF}_4$  crystal in aqueous solution. Combination with the solubility product rule, the relationship between the molar fraction of  $\text{Li}^+$  in the  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals and the molar fraction of  $\text{Li}^+$  in the initial solution can be easily understood. At the lower  $x$  ( $\text{Li}^+$  molar fraction in solution), it will have a much lower degree of supersaturation for  $\text{LiReF}_4$  than that of  $\text{NaReF}_4$  owing to the lower  $\text{Li}^+$  ion concentration in the initial solution and the larger solubility of  $\text{LiReF}_4$ . Therefore, there are most of  $\text{Na}^+$  ions and part of  $\text{Li}^+$  ions can combine with  $[\text{ReF}_4]^-$  to stable  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  in solution, leading to the larger negative deviation in  $\text{Li}^+$  molar fraction in the final  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals. Whereas at the higher  $x$  ( $x \geq 0.6$ ), it will have the higher degree of supersaturation for  $\text{LiReF}_4$  than that of  $\text{NaReF}_4$  owing to the higher  $\text{Li}^+$  ion concentration in the initial solution. Hence, the majority of  $\text{Li}^+$  ions and part of  $\text{Na}^+$  ions can be incorporated in the final  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals, resulting in the relative smaller positive deviation in  $\text{Li}^+$  molar fraction in the final  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals. As for the case at  $x=0.5$ , there are both higher degree of supersaturation for  $\text{LiReF}_4$  and  $\text{NaReF}_4$  due to the both higher concentrations of  $\text{Li}^+$  ion and  $\text{Na}^+$  ion in

the initial solution, it can ensure that the most of  $\text{Li}^+$  ions and the most of  $\text{Na}^+$  ions both be incorporated in the final  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals. As a result, the molar fraction of  $\text{Li}^+$  ions in the  $\text{Na}_{(1-x)}\text{Li}_x\text{ReF}_4$  microcrystals is almost to the same that one in the initial solution.
