Experimental Section

Chemicals and materials. Indium (III) chloride tetrahydrate ($InCl_3 \cdot 4H_2O$), sodium oleate ($C_{18}H_{33}NaO_2$), potassium bicarbonate ($KHCO_3$) and ethanol (C_2H_5OH) were all purchased from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China). GO was purchased from Shanghai Ashine Technology Development Co. Ltd (Shanghai, China). (1-Propanesulfonic acid 3-(trimethylsilyl) sodium salt, DSS) was purchased from Sigma-Aldrich. All the chemicals were used without further purification. Ultrapure Millipore water (18.2 MΩ) was used in all our experiments.

Synthesis of In(OH)₃-rGO hybrid. In a typical synthesis, 0.9 mmol of sodium oleate was firstly mixed with 40 mL of preformed GO aqueous suspension (2 mg/mL). After vigorous stirring for 30 min, 0.3 mmol of $InCl_3 \cdot 4H_2O$ was added into the above solution with another 30 min of stirring. Afterwards, the mixture was transferred into a 40 mL Teflon-lined autoclave, sealed and heated at 150 °C for 3 h. After naturally cooling down, the product was centrifuged and washed with ethanol three times and dried in vacuum at 45 °C overnight for further characterizations.

Synthesis of the In₂O₃-rGO hybrid. In a typical procedure, the as-obtained In(OH)₃-rGO hybrid was calcined at 400 °C for 5 min in air and then cooled down to room temperature.

Synthesis of In(OH)₃ and In₂O₃ nanobelts. The In(OH)₃ nanobelts were prepared using the same synthetic procedure as the synthesis of In(OH)₃-rGO hybrid except for the absence of GO. The In₂O₃ nanobelts were further obtained by treating the In(OH)₃ nanobelts at 400 °C for 5 min in air.

Synthesis of In₂O₃/rGO. In the preparation of In₂O₃/rGO, rGO was firstly obtained in the same way as in the synthesis of In(OH)₃-rGO hybrid without the addition of $InCl_3 \cdot 4H_2O$. Then 58 wt% of In₂O₃ nanobelts and 42 wt% of rGO were separately dispersed in 10 mL ethanol and stirred for 30 min at room temperature. Then these two solutions were mixed together under magnetic stirring for another 30 min. Afterwards, the mixture was obtained by centrifugation and then dried in vacuum at 45 °C.

Electrochemical measurements. All the electrochemical measurements were carried out in an H-cell (separated by Nafion 115 membrane) system. The Pt wire and Ag/AgCl (3 M KCl) electrode were used as the counter electrode and reference electrode, respectively. All potentials were measured against an Ag/AgCl reference electrode and were converted to values with reference to reversible hydrogen electrode (RHE) using E (vs. RHE) = E (vs. Ag/AgCl) + 0.21 V + 0.0591 × pH.

Prior to the electrochemical measurements, the working electrode was prepared. Typically, 5 mg of In_2O_3-rGO hybrid catalyst and 37.5 µL of Nafion solution (5 wt%) were dispersed in 2 mL of ethanol by sonicating for 1 h to form a homogeneous catalyst ink. Then, 320 µL of the catalyst ink was uniformly deposited on carbon papers of 1 cm × 1 cm to act as the working electrode. As a reference, the In_2O_3/rGO and In_2O_3/C catalysts ink were prepared using the similar procedure as that for In_2O_3-rGO hybrid catalyst ink. The linear sweep voltammetry (LSV) was performed in CO_2-saturated and N_2-saturated 0.1 M $KHCO_3$ aqueous solution from 0 V to -1.2 V at a scan rate of 10 mV s^{-1}. The electrochemically active surface area (ECSA) of the working electrodes were estimated according to the equation: ECSA = R_fS, where R_f is the roughness factor, S is the geometric area of the working electrode. The R_f can be determined by the relation $R_f = C_{dl}/60$ µF cm^{-1} based on the double-layer capacitance (C_{dl}) of a smooth oxide surface. C_{dl} was determined by measuring the capacitive current associated with double-layer charging from the scan-rate dependence of cyclic voltammogram (CV). The C_{dl} was estimated by plotting the Δj (j_a-j_c) at 0.75 V against the scan rates, the Δj could be acquired by cyclic voltammetry measurement under the potential windows of 0.7~0.8 V. The electrochemical impedance spectra of the samples were recorded with AC voltage with 5 mV amplitude at -0.7 V within the frequency range from 100 KHz to 100 mHz. Tafel slopes for formate production were calculated from the corresponding current densities at the potential range from -0.48 to -0.55 V and the formate Faradaic efficiency. The electrochemical reduction of CO_2 was carried out in CO_2-saturated 0.1 M $KHCO_3$ electrolyte (pH = 6.8) in the potential range of -0.5 V to -1.2 V at room temperature. After CO_2 was purged into the $KHCO_3$ solution for at least 30 min to remove

residual air in the reservoir, controlled potential electrolysis was conducted at each potential for 45 min. The oxygen generated at the anode was vented out of the reservoir. The gas products of CO_2 electrocatalytic reduction were monitored by an online micro gas chromatography (GC) (GC2014, Shimadzu, Japan) equipped with a TCD detector every 5 min. The durability tests were conducted at the potential of -1.2 V for 10 h. The $KHCO_3$ solution after electrolysis was collected and analyzed on a 400 MHz NMR spectrometer to quantify liquid products.

Calculations details. All the calculations were performed based on density functional theory (DFT) implemented in the VASP package.[1,2] The projector augmented wave method was used to describe the interaction between ions and electrons. The energy cutoff of plane wave basis sets for surface calculations are set as 400 eV. The nonlocal exchange correlation energy was evaluated using the Perdew-Burke-Ernzerhof (PBE) functional.[3] The van der Waals interactions is described using the semi-empirical DFT-D3 type of dispersion energy correction.[4,5] All the atoms were relaxed until the residual forces on all unconstrained atoms were less than 0.02 eV/Å. During frequency calculations, the adsorbates and directly connected In and O atoms were relaxed. $2 \times 2 \times 1$ and $2 \times 3 \times 1$ k-points grids are used for In_2O_3 (110) unit cell and (2×1) supercell calculations, respectively. HSE06 [6] functional is adopted for the calculation of work function and energy gap, which contains a screening of $\omega = 0.11$ bohr^{-1} to partition the Coulomb potential into short-range (SR) and long-range (LR) terms follows the form:

$$E_{xc}^{HSE}(\omega) = E_x^{HSE,SR} + E_x^{PBE,LR} + E_c^{PBE}$$

where

$$E_{xc}^{HSE,SR} = \frac{1}{4}E_x^{Fock,SR} + \frac{3}{4}E_x^{PBE,SR}$$

The adsorption energies of CO_2 were defined as

$$\Delta E_{ads}(CO_2) = E_{CO_2/In_2O_3} - E_{In_2O_3} - E_{(CO_2)}$$

Where E_{CO_2/In_2O_3}, $E_{In_2O_3}$ and $E_{(CO_2)}$ represent the total energies of the surface slab with the CO_2, the clean surface In_2O_3 (110) slab, and gas phase CO_2, respectively.

The reaction Gibbs free energy of each elementary step was defined as

$\Delta G = \Delta E + \Delta ZPE - T\Delta S$. ΔE is the reaction energy based on density functional calculations and ΔZPE is the energy change of zero point energy correction (*ZPE*). T is temperature and ΔS is the entropy change. Under standard conditions (pH = 0, p(H$_2$) = 1 bar, U = 0 V vs. SHE at 298.15 K), the Gibbs free energy of H$^+$ (aq) + e$^-$ equals to that of $\frac{1}{2}$ H$_2$ (g).[7] For adsorbed CO$_2$* and HCOO^{-*}, the vibrational frequencies of adsorbates were calculated to obtain ZPE contributions according to $ZPE = \sum_i \frac{1}{2} h\upsilon_i$, where υ_i is the frequency and *i* is the frequency number. For gas phase H$_2$ and CO$_2$, the values of entropy are obtained from the NIST database at room temperature.[8] And for adsorbed species, only the vibrational entropy (S_v) defined as

$$S_v = \sum_i R\{\frac{h\upsilon_i}{k_B T}[\exp(\frac{h\upsilon_i}{k_B T})-1]^{-1} - \ln[1-\exp(-\frac{h\upsilon_i}{k_B T})]\}$$ are taken into account,[9] where R = 8.314

J·mol^{-1}·K^{-1}, T = 298.15 K, h = 6.63*10^{-34}J·S, k$_B$ = 1.38*10^{-23} J·K^{-1}.

For the composition of rGO and In$_2$O$_3$(110) nanosheet, the charge transfer direction can be evaluated by the alignment of the band structures of rGO and In$_2$O$_3$(110). Based on HSE06 calculations, the band gap and the work function of In$_2$O$_3$(110) are calculated as 2.10 eV and 6.38 eV, respectively, which agree well with previous theoretical work.[10] According to the theoretical calculation of Priyank V. Kumar et al, the work function range of rGO with epoxy group is 4.35-5.60 eV.[11] In our work, The work function of rGO with different epoxy group coverages are also calculated as listed in Table S1. The work function of rGO increases with the oxygen coverage, and the work function of perfect graphene is 4.54 eV. So the electron will spontaneously run from rGO to In$_2$O$_3$ (110), as shown in Figure S15.

Instrumentation. TEM images were taken using a Hitachi H-7650 transmission electron microscope at an acceleration voltage of 100 kV. HRTEM and HAADF-STEM were carried out on a JEOL ARM-200F field-emission transmission electron microscope operating at 200 kV accelerating voltage. XRD patterns were recorded by using a Philips X'Pert Pro Super diffractometer with Cu-Kα radiation (λ = 1.54178 Å). Raman spectra were detected by a Renishaw RM3000 Micro-Raman system with a 514.5 nm Ar laser. The mass content of In$_2$O$_3$ in In$_2$O$_3$/rGO hybrid was determined by ICP-AES (Atom scan Advantage, Thermo Jarrell Ash, USA). XPS measurements were carried out on a VG ESCALAB MK II X-ray photoelectron

spectrometer with an exciting source of Mg Kα = 1253.6 eV. The binding energies obtained in the XPS spectral analysis were corrected for specimen charging by referencing C 1s to 284.6 eV. The liquid products were quantified by nuclear magnetic resonance (Bruker AVANCE AV III 400) spectroscopy. XANES spectra (C K-edge, and In M_2-edge) were measured at the beamline 12B of national synchrotron radiation laboratory (NSRL, Hefei).
