Electrical characterization

In the body text we show the electrical resistivities ρ and the carrier concentration n_e of TiS_2 grown by atomic vapor deposition (ALD).[S1–S3] Here is an overview of the detailed electrical parameters obtained by Hall measurements: These are a schematic of the specimen and the resulting geometric factors from the van-der-Pauw measurement (Figure SS1a), the Hall voltage V_H and Hall constant R_H (Figure SS1b) as well as the Hall mobility μ_H (Figure SS1c). For the van der Pauw specimen we deposit $200\,nm$ of TiS_2 by ALD onto a cleaned $1\,x\,1\,cm^2$ glass substrate with gold point contacts on each edge. For this we derived all Hall parameters and the resistivity.
Figure S1: **Hall parameters of 200nm TiS2 film.** (a) Sheet resistivity in a $1 \times 1\,cm^2$ Hall van-der-Pauw specimen. (b) The Hall voltage V_H and Hall constant R_H as function of the temperature T (measured at $100\,\mu A$ and $0.91\,T$ magnetic field). (c) Mobility μ_H as function of temperature.

Electrochemical characterization

All electrochemical studies were conducted in a standard three-electrode arrangement in an H-cell configuration (Figure S3). $200\,nm$ of TiS_2 on carbon paper are used to study the electrocatalytic activity (working electrodes, WEs). We use Ni as a counter electrode (CE) to improve the oxygen evolution. For our studies it was necessary to employ a hybrid solvent (acetonitrile and water) to address stability (TiS_2 can hydrolyze in all-aqueous media)[S1] and to improve the solubility of CO_2 (up to $0.2\,mol\,L^{-1}$). Furthermore, we found the presence of water advantageous to create a continuous electrolysis cycle with co-evolution of O_2 (in addition to CO-evolution on the cathode) on the Ni anode. As such we create an electrolysis CO_2 splitting to CO and O_2 ideal for long-term studies without risk of unwanted side-oxidation of the electrolyte (oxidation of EMIM-BF$_4$ and NBu$_4$-PF$_6$) or the co-solvent (oxidation of CH$_3$CN). To determine the reference potential we use a calibrated Ag/AgCl quasi reference electrode (QRE). The electrolyte is $0.1\,M$ NBu$_4$-PF$_6$ or 4% EMIM-BF$_4$ in acetonitrile-water. The water amount is set to 1%vol (or, $0.56\,mol\,L^{-1}$). The reference potential (calibration) of the QRE is measured referring the ferrocene/ferrocenium couple (Fc/Fc$^+$). We compared the standard potential $E_{QRE\,vs.\,Fc/Fc^+}$ in the CO_2-purged state, in $0.1\,M$ NBu$_4$-PF$_4$ or 4% EMIM-BF$_4$ in acetonitrile-water. The system CO_2, water and CH$_3$CN and the electrolyte will lead to a constant pH with only negligible changes. From the as-derived $E_{QRE\,vs.\,Fc/Fc^+}$

we calculated the standard reference potentials of the reversible hydrogen electrode (RHE, equation 1:

$$E_{RHE} = E_{QRE\,vs.\,Fc/Fc^+} + 0.641\,V + pH \cdot 0.0591\,V \qquad (1)$$

We show the calibration against Fc/Fc^+ (sweeps) inside the cyclic voltammetry plots (body text, Figure 4). The cell parameters/constants and the electrochemical surface area (ECSA) were studied by electrochemical impedance spectroscopy (EIS). Spectra were recorded between 100 mHz and 0.1 MHz with an ac-amplitude of 50 mV (Figures SS2 and SS3 and Table SS1). From the Bode-plot we derive the resistances (R_{el}, electrolyte, R_m, membrane/frit) and the working electrode capacitance (C_{WE}). The latter is used to estimate the surface factor of the electrochemical surface area (f_{ECSA} of carbon paper, equation 2) and to calculate the current density (j_{ECSA}) from the projected surface area. As reference capacitance we use $40\mu F\,cm^2$ (planar glassy carbon).[S4]

$$f_{ECSA} = \frac{C_{WE}}{C_{ref}} \qquad j_{ECSA} = \frac{j_{projected}}{f_{ECSA}} \qquad (2)$$
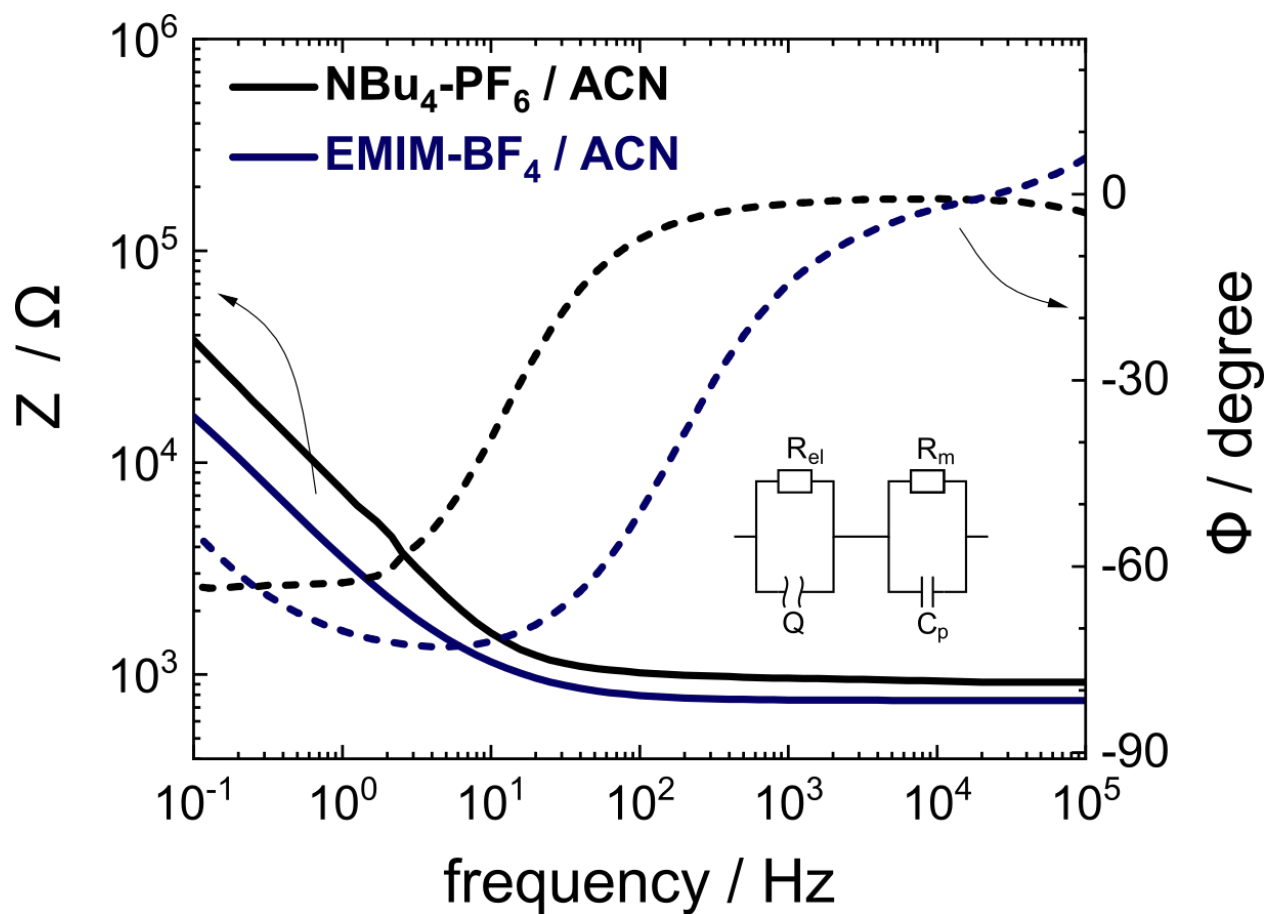

Figure S2: **Impedance data of electrolysis cell in NBu$_4$-PF$_6$ and EMIM-BF$_4$ electrolyte solution.** Bode-plot of the electrolysis cell used to derive the resistances (R_{el} and R_m) and the WE-capacitance (to further calculate the surface factor f$_{ECSA}$). Inset: (b) Equivalent circuit used to derive the cell constants R_{el}, R_m and C_{WE}. C_{WE} is crosschecked by j vs. scan rate, Figure S3 and used to calculate the ECSA.

Table S1: Cell constants measured from electrochemical impedance spectroscopy; values normalized to $1\,cm^2$.

electrolyte	WE	CE	R_{el}* / Ω	R_m* / Ω	C_{WE} / μF	f$_{ECSA}$
0.1 M NBu$_4$-PF$_4$	TiS$_2$	Ni	51.0	$4.82 \cdot 10^4$	186	4.65
4% EMIM-BF$_4$	TiS$_2$	Ni	27.5	$1.32 \cdot 10^4$	178	4.45

*electrolyte and membrane resistances

The working electrode capacitance (C_{WE}) was further determined using current density j at different scan rates (Figure S3a). The capacitance is derived at -0.2 V vs. Ag/AgCl QRE by taking the slope from j versus scan rate plot (Figure S3b). From this, we derive a similar capacitance as before measured by electrochemical impedance spectroscopy at $188\,\mu F\,cm^{-2}$.

Figure S3: **j vs. scan rate to determine the electrochemical surface area.** (a) ECSA-measurement of displacement currents in NBu$_4$-PF$_6$ on the working electrode at different scan rates. (b) Plot of the scan rates (taken at -0.2 V vs. Ag/AgCl QRE) versus the current densities j to derive the capacitance C_{WE}. The linear fit (slope) shows a similar value for carbon paper as reported by electrochemical impedance spectroscopy ($C_{WE} = 188\,\mu F\,cm^{-2}$).

Water and conductivity

In addition, we explored the effect of water on the ionic conductivity. The Bode-plot (Figure SS4) shows only a minor decrease of R_{el} between 1 and 10%$_{vol}$ water ($52.4\,\Omega\,cm^{-2}$ and $50.1\,\Omega\,cm^{-2}$, respectively).
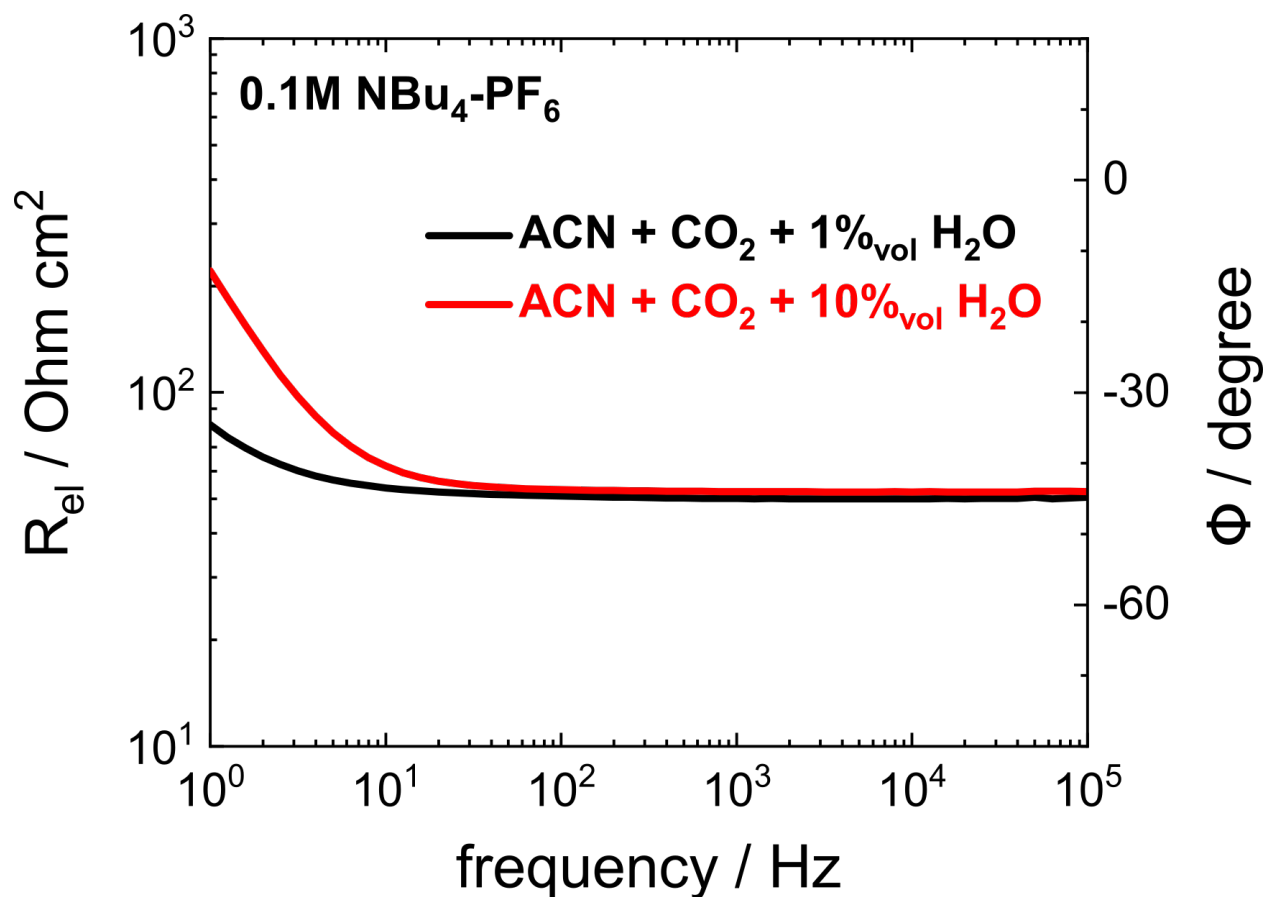

Figure S4: **R_{el} in NBu$_4$-PF$_6$ at 1% and 10% water content.** Bode-plot of R$_{el}$ shows little effect of water on the electrolyte conductivity (*i.e.* decrease of R_{el} from $(52.4\,\Omega\,cm^{-2}$ to $50.1\,\Omega\,cm^{-2})$.

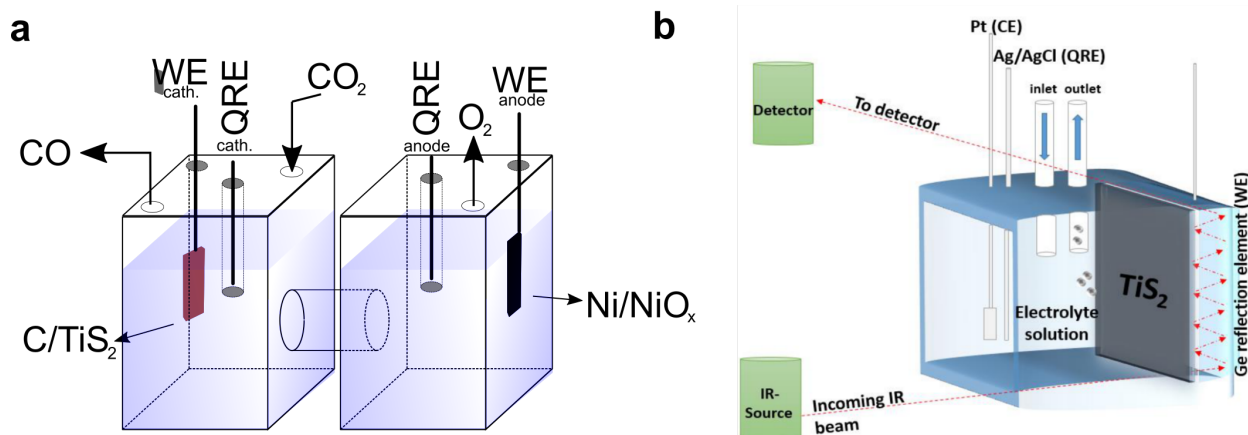

Figure S5: **Schematic of the cells used to study CO$_2$-splitting to CO and O$_2$.** (a) Electrolysis cell: For the anode side, a Ni/NiO$_x$ counter electrode (CE) is employed to activate the evolution of O$_2$ and to suppress unwanted degradation of the electrolyte and solvent.[S5–S7] (b) Spectroelectrochemical flow cell: Schematic of the in-situ ATR-FTIR internal reflection mode to explore the stability/mechanism of CO$_2$RR on TiS$_2$.
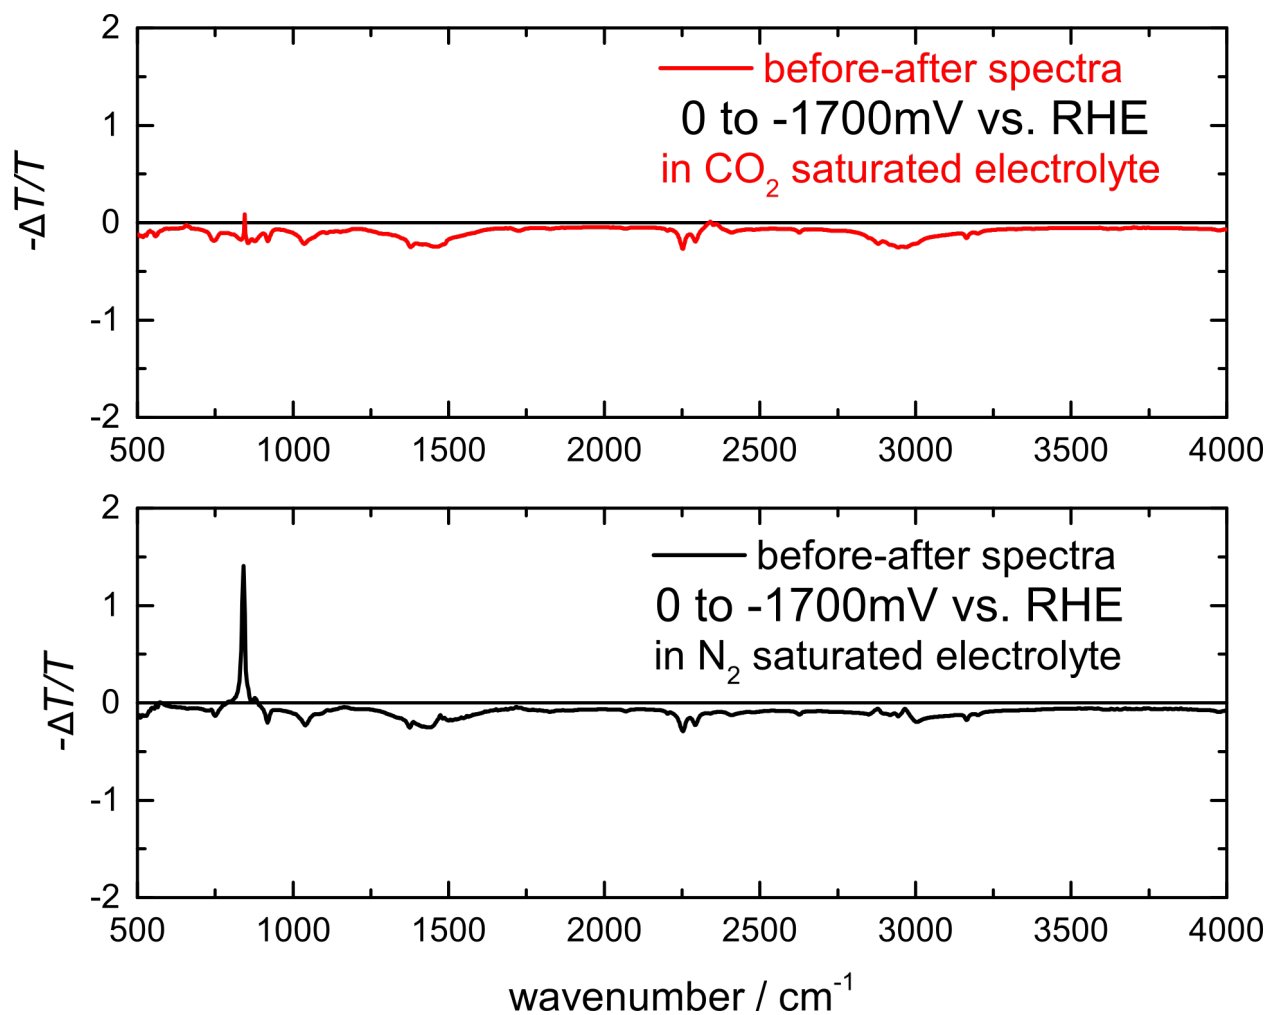

Figure S6: **In-situ ATR-FTIR spectroscopy employed to explore stability/reversibility.** Scan to maximum reduction potential (-1.7 V vs. RHE) and back (before-after-scan) in N_2 saturated and CO_2 saturated environment. In both cases, the response from TiS_2 shows the spectroscopic fingerprints of CH_3CN and the electrolyte (NBu_4-PF_6) and, in presence of CO_2, accumulation of CO_2 on the surface.

In-situ FTIR

The scheme/function of the in-situ FTIR setup is depicted in Figure S5b: It comprises *(i)* a germanium parallelepiped serving as the infrared reflection element for attenuated total reflection mode (ATR), *(ii)* the electrocatalysts (200 nm TiS_2) deposited on top of this element, *(iii)* the flow-cell mounted onto the reflection element and *(iv)* the electrical and solution supply tubes. The entire flow cell is made from Teflon. The feedthroughs for the tubes are tightened using wax. The cell is placed into the FTIR-probe space onto a custom designed holder. We tighten the cell using a Teflon bolt and a rubber o-ring between flow-cell and germanium-TiS_2. The electrical contacts are provided by thin copper wires outside the FTIR-setup. During measurement we continuously supply fresh CO_2-saturated electrolyte and measure the IR-response as function of time and electrochemical potential (and current). The ATR-mode delivers a qualitative insight to the surface reactions related to CO_2RR. In addition we see accumulation/depletion of the electrolyte and solvent. The estimated penetration depth of the evanescent wave is a few µm at the interface TiS_2/electrolyte. Quantitative estimations have to be considered with care, since the penetration depth is also dependent on the wavelength. We subsequently interpret our spectra only surface- and near-surface-sensitive (*i.e.* adsorption on the surface and adjacent Helmholtz-layer on the TiS_2/solution interface). The difference spectra -ΔT and differential spectra -$\Delta T/T$ depict the changes experimentally observed within these layers. Bulk changes in TiS_2 (massive degradation or dissolution/degradation from the electrode) can be clearly excluded within the reported potential window between 0 and -1720 mV vs. RHE (Figure SS6).[S8–S10] All changes seen in this stability scans relate either to the electrolyte, the acetonitrile and, in CO_2-saturated solution, to CO_2. Above these potential windows we cannot exclude the dissolution/reaction of the electrocatalyst and the germanium with the corresponding electrolyte.
Figure S7: **Analysis of CO₂RR products in the head space.** Gas chromatograms show the gaseous product distribution at -0.11 V vs. RHE (zero overpotential for CO, reference scan with hydrogen evolution). At -0.5 V vs. RHE (or 0.39 V overpotential) we detect a similar amount of H_2 and preponderantly evolution of CO.

Chromatographic CO detection

From chronoamperometric scans we detected the onset of CO evolution and the quantitative determination of CO to calculate the Faradaic efficiencies. We present that at the reported onset for CO evolution at $5\,\mathrm{mA\,cm^{-2}}$ at -0.5 V vs. RHE (or 0.39 V overpotential), a distinct CO peak appears (correlating to 83% Faradaic yield). At the thermodynamic equilibrium for CO evolution (-0.11 mV vs. RHE), only hydrogen is detected. The hydrogen content (and as such j_{H_2}) remains approximately constant between -0.11 and -0.5 mV vs. RHE (nn) which underlines the selectivity of TiS_2 for CO.

Addendum: Mechanistics

As proposed in Figure 3a,b (body text), we further show the difference spectra in the thiole fingerprint regime (S-H bonding) that emerges between 1550-1590 $\mathrm{cm^{-1}}$. Similar features have been reported for MoS_2[S11] for hydrogen evolution. We indicate this analogy in the differnce scan, since a minor fraction of our product is also hydrogen (Figure SS8).

Addendum: Comparison

Ag and Au (thin films on glass by physical vapor deposition) are compared to TiS_2 using the same electrolyte (NBu_4-PF_6) (Figure SS9).
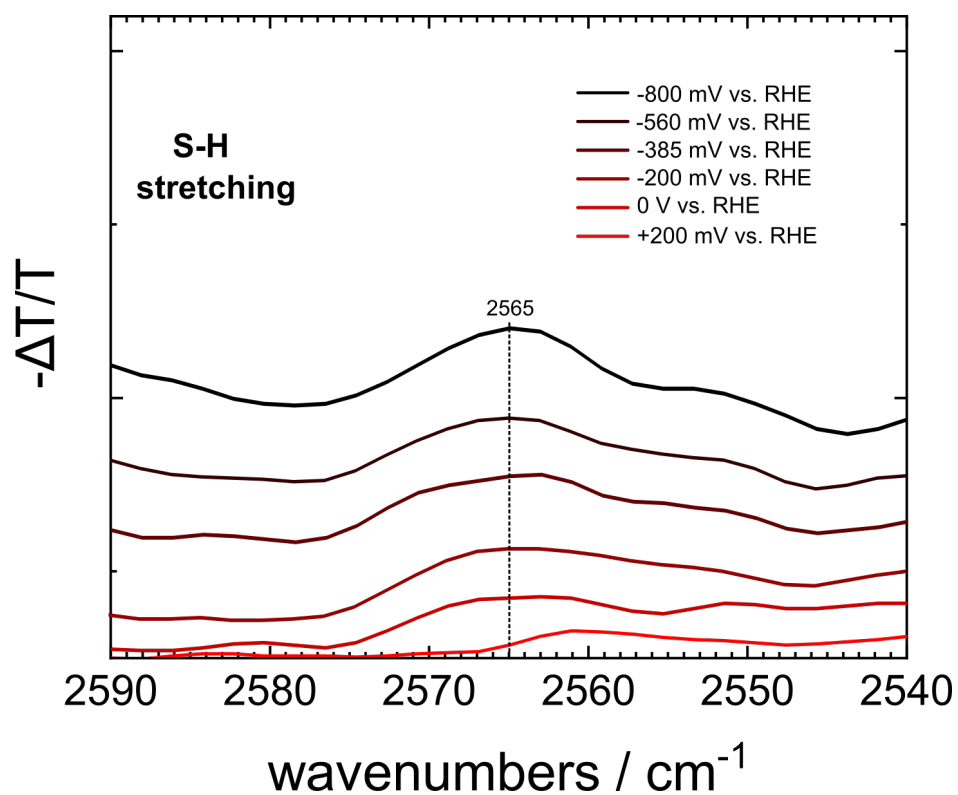

Figure S8: **Fingerprint regime for thiole in the differential scan of the in-situ ATR-FTIR system**. The spectra reveal a distrinct S-H stretching at $1565\,\mathrm{cm^{-1}}$ upon increasing cathodic bias (co-evolution of hydrogen besides CO).
Figure S9: **Voltammograms of Au, Ag and TiS$_2$ in the same electrolyte for comparison.**
