1. More details of the model and its configuration

The parameterizations of NPF rates were developed in several previous studies based on experiments in the CLOUD (Cosmics Leaving Outdoor Droplets) chamber,[1-4] with a couple of updates in our previous study.[5] The NPF rates at 1.7 nm mobility equivalent diameter are calculated as the sum of the following parametrizations:

(1) Binary neutral (indicated by b, n) and ion-induced (b, i) NPF involving sulfuric acid:

$$J_{SA} = k_{b,n}(T)[H_2SO_4]^{p_{b,n}} + k_{b,i}(T)[H_2SO_4]^{p_{b,i}}[n_-]$$

where the $k(T)$ is a temperature-dependent prefactor and includes free-fitting parameters (see equations below), p is a constant free parameter, and $[n_-]$ is the concentration of negative ions.

(2) Ternary neutral (indicated by t, n) and ion-induced (t, i) NPF involving sulfuric acid and NH₃:

$$J_{SA,NH3} = k_{t,n}(T)f_n([NH_3],[H_2SO_4])[H_2SO_4]^{p_{t,n}} \\ + k_{t,i}(T)f_i([NH_3],[H_2SO_4])[H_2SO_4]^{p_{t,i}}[n_-]$$

where the $f([NH_3],[H_2SO_4])$ is a function of the ammonia and sulfuric acid concentrations, also involving free-fitting parameters.

All the $k(T)$ in (1) and (2), for temperatures T in Kelvin, are given by:

$$\ln k_{(x,y)} = u_{(x,y)} - \exp\left(v_{(x,y)}(T/1000 - w_{(x,y)})\right)$$

where $x = b$ or t (binary and ternary) and $y = n$ or i (neutral and ion-induced). The functions $f_y([NH_3],[H_2SO_4])$ are

$$f_y([NH_3],[H_2SO_4]) = [NH_3]/\left(a_y + [H_2SO_4]^{p_{t,y}}/[NH_3]^{p_{A,y}}\right)$$

(3) NPF of organics with sulfuric acid:

$$J_{SA-org} = k_{SA-org}[H_2SO_4]^2(33.0 \times 0.667[ELVOC_{O:C>0.4}])$$

where $[ELVOC_{O:C>0.4}]$ refers to the concentration of ELVOC with O:C >0.4 from the oxidation of monoterpenes, and k_{SA-org} is a fitted parameter. The factor 0.667 corrects for the large yield

48   of ELVOC from α-pinene (a type of endocyclic monoterpene) compared to other monoterpenes,

49   as endocyclic monoterpenes comprise nearly 2/3 of all monoterpene emissions over the Amazon.[6]

50   The adjustment factor of 33.0 is the ratio of total monoterpene oxidation products to ELVOC with

51   O:C >0.4 under the environmental conditions where the parameterizations were developed.[5]

52   (4) NPF from organics alone, a sum of neutral ($J_{n,org}$) and ion-induced ($J_{iin,org}$) components:

53   $$J_{n,org} = a_1(3.6 \times 0.667[ULVOC_{O:C>0.4}])^{a_2+a_5/(3.6\times0.667[ULVOC_{O:C>0.4}])}$$

54   $$J_{iin,org} = a_3(3.6 \times 0.667[ULVOC_{O:C>0.4}])^{a_4+a_5/(3.6\times0.667[ULVOC_{O:C>0.4}])}[n_\pm]$$

55   where $[ULVOC_{O:C>0.4}]$ refers to the concentration of ULVOC with O:C >0.4 from the oxidation

56   of monoterpenes and is given here for convenience in units of 10^7 molecules cm^{-3}, $[n_+]$ is the

57   ion concentration (equal to $[n_-]$, but ions of both signs participate in this NPF process), and a_i

58   are free parameters. The factor 0.667 has the same meaning as described above. The adjustment

59   factor of 3.6 is the ratio of highly oxygenated organic molecules (HOMs) to ULVOC with O:C

60   >0.4 under the environmental conditions where the parameterizations were developed.[5]

61   (5) In a sensitivity simulation, we also consider the NPF of H_2SO_4 with amines. Assuming all

62   amines nucleate at the same rate as dimethylamine (DMA), the NPF rate is given by:

63   $$J_{SA-Amine} = k_{SA-Amine-1}\big([DMA]/(2.5 \times 10^7)\big)[H_2SO_4]^{3.7}$$

64   for $[DMA] > 2\times10^8$ cm^{-3}, and

65   $$J_{SA-Amine} = k_{SA-Amine-}\big([DMA]/(2.5 \times 10^7)\big)^{4.36}[H_2SO_4]^{3.7}$$

66   for $[DMA] < 2\times10^8$ cm^{-3}. $k_{SA-Amine-1}$ and $k_{SA-Amine-}$ are fitted parameters.

67   The values of all parameters in the equations above are given in Table S1 (shown below).

68   Attention must be paid to the units of the gas concentrations, specified in the table footnotes.

69   The parameterizations above do not consider the impact of relative humidity on organic-

70   mediated NPF. It is not easy to investigate the impact of relative humidity on NPF during the wet

71   season of the Amazon based on available observational data because the relative humidity is

72   almost always quite high in the boundary layer—the region this study focuses on and most

73   observational data are available in. The relative humidity within our domain is as high as

74   89.6±11.6% at the surface level and 87.5±9.2 at 500 m height during our simulation period (Table

75   S3). From the laboratory perspective, Li et al.[7] investigated the effect of relative humidity on the

76   formation of highly oxygenated organic molecules and new particles in a flow tube reactor. They

77   found that as relative humidity increases from ∼3% to ∼92%, the total SOA number

78   concentrations decrease by a factor of 2–3, suggesting that high RH might inhibit pure-organic

79   NPF. However, the mechanisms for this inhibition remain unclear. Also, the conclusion derived

80   from pure-organic NPF by Li et al.[7] may not be directly applicable to the NPF of H_2SO_4 with

81   organics—the main NPF pathway in our region of interest. Besides, since the relative humidity in

82   the wet season of the Amazon has a relatively small variability, the effect of relative humidity on

83   NPF in this region is expected to be smaller than the effect shown by Li et al.[7] Because of these

84   reasons, we do not consider the effect of relative humidity on organic-mediated NPF in our model.

85   We are interested in considering this effect when more quantitative and mechanistic experimental

86   evidence becomes available.

87   As described in the main text, we use the MOSAIC (Model for Simulating Aerosol Interaction

88   and Chemistry) aerosol module[8] in our simulation. We changed the accommodation coefficient

89   for the condensation of H_2SO_4 from 0.1 in the original MOSAIC module to 1.0, following Hanson[9].

90   The aqueous-phase chemistry is based on the Carnegie Mellon University (CMU) scheme of Fahey

91   and Pandis[10]. The biogenic emissions are calculated online using the Model of Emissions of Gases

92   and Aerosols from Nature (MEGAN v2.1)[11] that has been recently coupled within the land surface

93   scheme CLM4 in WRF-Chem.[12] We reduce the monoterpene emissions predicted by MEGAN

94　v2.1 by a factor of 2 so that the simulated magnitude of monoterpene concentrations generally

95　agrees with aircraft observations (see the main text). A previous modeling study over the Amazon

96　also suggested that the simulated monoterpene concentrations using MEGAN v2.1 overpredicted

97　observations by about a factor of 2.[13] The vertical resolution of the simulation includes 45 layers

98　from the surface to 50 hPa with denser layers at lower altitudes. The physical options, as well as

99　initial and boundary conditions used in our simulations, follow Zhao et al.[5]

2. Sources of observational data

101　We evaluate the model simulations using measurements obtained in the GoAmazon

102　(Observations and Modelling of the Green Ocean Amazon) campaign.[14-16] The pollution plumes

103　from Manaus generally follow the easterly trade winds during the simulation period. The

104　Gulfstream 1 (G-1) aircraft was deployed during certain days of the GoAmazon campaign to

105　measure aerosol characteristics downwind (west) of Manaus. As described in the main text, on

106　March 11, 13, and 14, the aircraft flight track passed over Manaus or intersected its pollution plume

107　perpendicular to the prevailing wind direction 4–5 times (Transects P0 to P3/4 in Fig. 1) at

108　increasing distances from Manaus at an altitude of 500–800 m. Based on the average wind speed

109　in the plume, on March 11, the transport times from Transect P0 (right above Manaus) to Transects

110　P1, P2, and P3 are about 1.26 h, 2.34 h, and 3.77 h, respectively. On March 13, the transport times

111　from P0 to P1, P2, P3, and P4 are about 1.15 h, 2.26 h, 3.45 h, and 4.78 h, respectively. On March

112　14, the transport times from P0 to P1, P2, P3, and P4 are about 1.06 h, 2.08 h, 2.71 h, and 4.28 h,

113　respectively. On March 12, the flight is special in that the plume transects were made in the

114　southernmost parts of the flight tracks (cf. middle parts for other flights) and turn-around flight

115　legs were made to achieve more effective plume transects; the aircraft still periodically passed

116　through in-plume and background air but Transects P0–P3 are not located increasingly farther

117 downwind as in other flights (see Fig. 1). We use total particle number concentrations measured

118 by a condensation particle counter (CPC, TSI model 3025, cutoff diameter 3 nm) and particle size

119 distributions ranging from 10 nm to 400 nm in diameter characterized by a fast integrated mobility

120 spectrometer (FIMS) at a time resolution of 1 second.[15, 17] We also make use of monoterpene

121 concentrations measured by an Ionicon quadrupole high-sensitivity proton-transfer-reaction mass

122 spectrometer (PTR-MS) onboard G-1.[16] Moreover, we employ measurements of H_2SO_4 by a

123 hydroxyl radical chemical ionization mass spectrometer (CIMS) at the T3 surface site downwind

124 of Manaus (Fig. 1)—the only available H_2SO_4 measurements during the GoAmazon campaign.[18]

125   Particle number concentration measurements at the T1 surface site in the urban area of Manaus

126 are not available for the simulation period (March 6–15, 2014). Therefore, we employ the

127 measurements during March 6–15 of 2016 made by a scanning mobility particle sizer (SMPS, TSI

128 model 3081) for particles with a diameter of 10–450 nm and conduct additional simulations with

129 exactly the same model configurations during this period to compare with the measurements. Note

130 that the CPC and FIMS aboard the G-1 aircraft and the SMPS at the T1 site are all located behind

131 a dryer. As a result, the sampling relative humidity has remained less than 40% for the whole field

132 campaign, which effectively minimized the potential impact of ambient relative humidity or water

133 supersaturation. For NH_3, no available observations are found within the modeling domain, thus

134 we use NH_3 concentration measurements by a wet-annular denuder at a site in southwest Amazon

135 during the wet season of 2002[19] as a proxy.

136 **3. Supplementary information about model-observation comparison**

137   In the main text, we compared simulated vs. observed particle size distributions (Fig. 3). Since

138 this comparison is limited to particles larger than 10 nm in diameter due to the limitation of FIMS,

139 we further show in Fig. S11 observed particle number concentrations in the diameter range of 3–

140   10 nm by the G-1 aircraft as well as simulated concentrations during four flights on March 11–14.

141   The observed particle number concentrations between 3 nm and 10 nm are derived from the

142   difference between two CPCs that measure particles larger than 3 nm and 10 nm, respectively.

143   First, we note that the observed high numbers of particles between 3 and 10 nm in the plumes

144   do indeed confirm that a large fraction of the particle concentrations is probably contributed by

145   NPF. Without NPF, the primarily emitted particles would have grown to larger sizes when they

146   were transported to the locations where they were observed by the G-1 aircraft (see the blue lines

147   in Fig. 3).

148   Second, we compare the modeled and observed concentrations. It is very challenging for

149   mainstream models to capture the particle distribution below 10 nm because such small particles

150   are very sensitive to even small changes in condensational growth and coagulational scavenging.

151   In our base-case simulation ("inorg+org_R2D-VBS"), the model captures the peak number

152   concentration in the range of 3–10 nm in some of the transects but generally underestimates the

153   peak concentrations in most transects. One likely reason for this bias is that the current model

154   assumes instantaneous equilibrium for gas-particle partitioning of organics instead of considering

155   kinetic partitioning for aerosol growth processes.[20, 21] Another possible reason is that we used a

156   highly condensed 2-bin Volatility Basis Set (VBS) approach to simulate the SOA formation from

157   all precursors other than monoterpenes, including anthropogenic volatile organic compounds

158   (VOC), non-monoterpene biogenic VOC, evaporated primary organic aerosol (POA), and

159   intermediate volatility organic compounds (IVOC). In this simplified scheme, the oxidation

160   products from each type of precursor are assumed to possess the same volatility (C* of 0.01 μg

161   m^{-3} for the oxidation products of evaporated POA and IVOC and 1.0 μg m^{-3} for the oxidation

162   products from anthropogenic VOC and non-monoterpene biogenic VOC), which may bias the size-

163 dependent growth rates. For example, Zaveri et al.[22] recently showed that assuming the

164 condensable vapors to have low volatility may cause small particles to grow too fast and thus lead

165 to underestimation of the concentration of small particles. In our ongoing work, we are trying to

166 incorporate kinetic organic partitioning in WRF-Chem and simulate the non-monoterpene organic

167 chemistry using an updated 4-bin VBS from Shrivastava et al.[13], which we hope will alleviate the

168 underestimation of particles between 3 nm and 10 nm.

169   To show that the above bias should not affect the main conclusion of this study regarding the

170 source of particle number, we conduct two sensitivity simulations in which we artificially reduce

171 the particle growth rate either in the entire size range ("slow growth") or only in the size range

172 below 10 nm ("slow growth below 10 nm") to allow more particles to stay in the range of 3–10

173 nm. Specifically, we assume that only 50% (cf. 100% in the base-case simulation) of the excessive

174 organic vapor (i.e., gas concentration before partitioning − equilibrium gas concentration) will

175 condense to the particle phase in the specified size range in each time step. Fig. S11 shows that

176 both scenarios show higher particle number concentrations between 3 nm and 10 nm compared to

177 the base-case simulation, leading to a much closer agreement with observations, though biases still

178 exist. Fig. S12 further illustrates the fractional contribution of NPF within the modeling domain to

179 particle number concentrations on a 2-km high vertical cross section which extends westward from

180 Manaus to 200 km downwind in the base case and two sensitivity scenarios. The contribution of

181 NPF is quantified using the difference in simulated particle concentrations between one of the

182 three scenarios and a hypothetical scenario without NPF ("nonuc" in Table S2). All three scenarios

183 show similar relative contributions of NPF to particle number concentration in the areas downwind

184 of Manaus, suggesting that the bias in particle growth that leads to the underestimation of 3–10 nm

185 particles in our current model is not likely to affect our main conclusion that NPF makes the most

186 important contribution to particle number in most of the downwind areas.

187   We note that the particle number concentrations (> 3 nm) for the "inorg" scenario are sometimes

188 lower than those for the "nonuc" scenario, as shown in Fig. 2. This is probably because the changes

189 in aerosol fields due to inorganic NPF could affect the meteorological fields by interacting with

190 radiation and clouds, which may further perturb particle concentrations at other times and

191 locations. Since the rates of inorganic NPF are small at many times and locations, the accumulated

192 perturbation over time could dominate over the direct particle formation in some circumstances,

193 leading to occasional lower particle number concentrations in the "inorg" scenario than in the

194 "nonuc" scenario. We also note that the simulated particle number at P3 on March 11 is

195 significantly lower than the observed value (Fig. 3a). The main reason is that the simulated

196 centerline of the pollution plume was shifted to some extent relative to the observed location (see

197 Fig. 2a), probably because of uncertainties in the simulated wind direction. As a result, the model

198 underestimates observed particle number concentrations near the location of the observed pollution

199 plume centerline.

200   As mentioned in the main text, we conduct additional simulations with the same model

201 configurations for March 6–15 in 2016 to compare with measurements at the T1 site. Here we

202 calculate the statistics of major meteorological variables within the modeling domain at the surface

203 level and 500 m height during our main simulation period (March 6–15, 2014) and the above

204 supplementary simulation period, as summarized in Table S3. The temperature and relative

205 humidity are very similar during the two simulation periods. The wind speed is also similar—the

206 mean wind speed is slightly larger in the simulation period of 2014 but the standard deviation is

207 very close in the two periods. The size distribution simulated by the base case ("inorg+org_R2D-

208 VBS") generally agrees with observations at T1, with a certain level of overestimation in the range

209 of 20–60 nm and underestimation in smaller and larger sizes (Fig. S4). As we discussed above, we

210 expect that the size distribution could be further improved after we incorporate in WRF-Chem

211 kinetic particle growth and improved volatility distribution of organic aerosols in our ongoing

212 work.

4. Relationships between NPF rates and particle number concentrations

214   The NPF rates shown in Fig. 5 and Fig. S6 are relatively low compared to many field

215 observations[23, 24] because they are averaged during the entire simulation period (March 6–15,

216 2014) and the data in Fig. 5 are further vertically averaged below 2 km. In contrast, observational

217 studies usually report only the NPF rates during strong NPF events.[23, 24] Fig. S13c shows hourly

218 average NPF rates on a 2-km high vertical cross section that extends westward from Manaus to

219 200 km downwind during the simulation period. We can see that high hourly average NPF rates

220 larger than 10 cm^{-3} s^{-1} are frequently simulated by the model.

221   We have also conducted additional analysis on the relationships between NPF rates and particle

222 number concentrations, as shown in Fig. S13. Fig. S13a exhibits the time-averaged NPF rate on

223 the aforementioned vertical cross section and Fig. S13b exhibits the time-averaged particle number

224 concentration increase due to NPF, which is quantified using the difference between the base case

225 ("inorg+org_R2D-VBS") and the scenario without NPF ("nonuc"). Fig. S13c further shows hourly

226 average NPF rate and increased particle number concentration on the cross section. The increased

227 particle number concentrations due to NPF are generally larger in areas with larger NPF rates.

228 There is a statistically significant positive correlation between the two with a correlation

229 coefficient of 0.619 and a p-value < 0.001 (Fig. S13c). However, the relationships are complicated

230 by two factors. First, a large NPF rate is simulated at the surface of the city center but the increase

231 in particle number concentration is relatively small mainly because of a large coagulational loss

232 caused by direct particle emissions. Second, particles observed in a certain location are not

233 necessarily formed locally but may be transported from upwind areas by the prevailing easterly

234 wind. As a result of the two factors, the increased particle number concentrations due to NPF peak

235 about 30 km downwind of the city center while the NPF rates peak near the city center (Fig.

236 S13a,b). Also, as a result of the two factors, the increase in particle number concentrations has a

237 large variability even for a given NPF rate (Fig. S13c).

238 **5. Details of the sensitivity analysis**

239 We showed in Results and Discussion that primary particle emissions only account for a small

240 fraction of particle number concentration downwind of Manaus. Compared with the particle size

241 distribution used in many previous regional modeling studies,[25-29] the size distribution used in this

242 study results in relatively large total particle number emissions (see Methods and Data). To test

243 potential uncertainties that may lead to even higher particle number emissions and hence a larger

244 contribution to ambient particle number concentrations, we design two sensitivity scenarios by

245 perturbing the total mass emissions ("nonuc_emis*4") and size distribution ("nonuc_emis_finer")

246 on the basis of the scenario without any NPF ("nonuc"). In the "nonuc_emis*4" scenario, we

247 increase the primary particle mass emissions by a factor of 4 while keeping the size distribution

248 unchanged. The particle size distribution used in this study is a superposition of two lognormal

249 distributions with an Aitken mode and an accumulation mode. In the "nonuc_emis_finer" scenario,

250 we reduce the Aitken-mode median diameter of urban sources from 25 nm to 12 nm. The reason

251 is that some emission measurements suggested that the primary particles from certain types of

252 vehicles might have a peak diameter of 10–25 nm,[30-32] smaller than 25 nm assumed for urban

253 emissions in this study. While the effective particle size of emissions at a 10-km grid spacing will

254   be larger than that of fresh emissions (see Methods and Data) and thus the effective size is unlikely

255   as small as 12 nm, we use this small size as a sensitivity test to examine the potential upper bound

256   of particle number emissions. Particle measurements at the T1 surface site in urban Manaus

257   provide a useful constraint for the estimate of primary particle emissions. Figure S3 shows that

258   both sensitivity scenarios overestimate the particle number concentration at the T1 site by a factor

259   of 2.5–3.2 even without considering NPF. This indicates that the particle number emissions in

260   these two scenarios are likely too high. Even so, Fig. S8 shows that the model still substantially

261   underestimates the aircraft-measured particle number concentration in the Manaus plumes by

262   nearly one order of magnitude. These results indicate that, even with the potential upper bound of

263   the particle number emission estimates, the primary particle emissions are not likely the main

264   sources for the high particle number concentrations in the pollution plumes from Manaus.

265   Apart from primary emissions, our results also indicate that inorganic NPF pathways make a

266   minor contribution to particle number downwind of Manaus. To investigate the factors that could

267   potentially lead to a larger contribution from inorganic NPF, we conduct two additional sensitivity

268   simulations ("inorg_NH$_3$*3" and "inorg_amine") based on the scenario of "inorg". Among the

269   precursors for inorganic NPF, the concentrations of NH$_3$ are subject to a relatively large

270   uncertainty partly due to very limited measurements over the Amazon. The "inorg_NH$_3$*3"

271   scenario is the same as "inorg" except that the NH$_3$ concentrations are elevated by a factor of 3.

272   The NPF of H$_2$SO$_4$ and amines has also been shown to be an appreciable pathway in certain

273   polluted environments.[33, 34] In the "inorg_amine" scenario, we provide a first-order estimate of the

274   potential contribution of H$_2$SO$_4$+amine NPF by incorporating the parameterization developed by

275   Dunne et al.[1] using data from the CLOUD chamber.[35] The amine concentrations have been

276   modeled by several studies with very similar methods; they all derived the amine emission

277   inventory by scaling down ammonia emissions using sector-specific factors.[1, 36, 37] Here we apply

278   the ratio of amine concentration to ammonia concentration simulated by Dunne et al.[1] over our

279   domain to the WRF-Chem/R2D-VBS simulated ammonia concentrations to estimate the amine

280   concentrations, and subsequently use the estimated amine concentrations to calculate the

281   H_2SO_4+amine NPF rate. Note that this scenario merely serves as a rough estimate of the potential

282   contribution of amines rather than a rigorous quantification of the NPF rate. Figure S9 reveals that

283   both the "inorg_NH$_3$*3" and "inorg_amine" scenarios only slightly amplify simulated particle

284   number concentrations relative to "inorg", which are still far below the concentrations observed

285   by the G-1 aircraft. These results reinforce our findings that inorganic NPF is unlikely the main

286   source of the particle number downwind of Manaus and suggest that our conclusions are robust.

287   The above sensitivity simulations, by testing the potential upper bounds of primary particle

288   emissions and inorganic NPF, increase our confidence that organic-mediated NPF probably acts

289   as the most important source of particle number downwind of Manaus. A sophisticated model

290   representation of organic-mediated NPF is crucially important for reasonably estimating its

291   contribution in polluted environments. Here we conduct two sensitivity simulations to show that

292   previous more simplified model treatments may lead to substantial bias in simulated NPF rates. In

293   the first simulation ("inorg+org_simple"), we assume that the organics contributing to NPF are a

294   fixed fraction of all monoterpene oxidation products, following the common practice of many

295   previous studies.[1, 4, 27, 38-40] The specific fixed fractions we used are from Gordon et al.[4] Figure S10

296   shows that this sensitivity run overestimates the G-1 observed particle number concentrations in

297   Manaus plumes by 1–1.5 orders of magnitude. A major reason, among others, is that this simple

298   treatment fails to capture the strong condensation sink of ULVOC/ELVOC in pollution plumes

299   due to their extremely low volatilities. In another sensitivity scenario ("inorg+org_R2D-

300   VBS_uniauto"), we apply an older version of the Radical 2D-VBS used in Zhao et al.[5] The

301   difference between the two versions is that the older version used a uniform autoxidation rate for

302   all RO_2 of the same generation. Figure S10 reveals that this scenario significantly underestimates

303   peak particle number concentrations in Manaus plumes by over one order of magnitude, indicating

304   that the prompt ELVOC formation through rapid autoxidation is critically important to effectively

305   compete with the condensation loss in urban plumes and to produce a considerable number of new

306   particles. While a uniform autoxidation rate can reasonably simulate the particle formation in

307   pristine conditions,[5] an appropriate representation of diversity in ELVOC formation rate is

308   necessary for polluted regions with a large condensation loss. The inorganic species involved in

309   NPF comprise a relatively small set; the organics are numerous, spanning a wide range in volatility

310   and also reactivity. The Radical 2D-VBS represents a substantial simplification over a full

311   chemical description. Our results reveal that further reducing the complexity much beyond this

312   point introduces measurable errors into real-world model outputs.

6. Discussion of the potential impact of other precursors and processes

313

314   In our current model, we use monoterpenes as the main precursors to drive organic-mediated

315   NPF, because monoterpenes have been well recognized to be an important contributor to NPF

316   since the oxidation of monoterpene produces a significant amount of ULVOC and ELVOC. It is

317   noted, however, that other organic precursors may also have (enhancement or suppression) effects

318   on NPF.

319   In contrast to monoterpenes, isoprene has been much less frequently observed to trigger NPF[41]

320   but has been frequently shown to suppress NPF events.[42-44] Regarding NPF triggered by isoprene,

321   Inomata et al.[41] showed that the ozonolysis of isoprene produces stabilized Criegee intermediates

322   and subsequently oligomeric hydroperoxides, which contribute to NPF under dry conditions.

323   However, the isoprene concentrations used in that experiment (~2 ppm) are approximately 3 orders

324   of magnitude higher than the isoprene concentrations observed in our region of interest (0.43–2.37

325   ppb).[16] Besides, Inomata et al.[41] showed that the NPF triggered by isoprene oxidation products is

326   substantially suppressed when relative humidity is larger than 68%. The relative humidity within

327   our domain is as high as 89.6±11.6% at the surface level and 87.5±9.2 at 500 m height during our

328   simulation period (Table S3), which is high enough to largely suppress isoprene-induced NPF.

329   Compared with the limited evidence for NPF driven by isoprene, more studies have revealed that

330   isoprene suppresses the NPF triggered by monoterpene oxidation products,[42-44] probably because

331   isoprene reduces the yield of highly-oxygenated dimers with about 20 carbon atoms that drive NPF

332   while increasing the production of "heterodimers" with about 15 carbon atoms (isoprene-

333   monoterpene cross reaction products).[44] For these reasons, we conclude that isoprene is not likely

334   to play a dominant role in driving NPF over the Amazon, but future research is still needed to

335   quantify the effects of isoprene on NPF rates. In addition, some studies have reported that

336   sesquiterpenes might make a noticeable contribution to NPF despite their much smaller

337   concentrations than monoterpenes,[45] but it is still difficult to accurately quantify their contribution

338   based on currently limited results. More recently, it was found that the oxidation of anthropogenic

339   organic precursors may also produce oxidation products with sufficiently low volatility to trigger

340   NPF in polluted environments.[46, 47] For example, Wang et al.[47] showed that the oxidation products

341   of toluene have a similar volatility distribution to that of α-pinene oxidation products, while the

342   oxidation products of naphthalene are even less volatile than those from toluene or α-pinene. Their

343   importance for NPF relative to biogenic precursors, however, remain largely unknown because 1)

344   the yields of ULVOC/ELVOC from anthropogenic precursors remain unclear; and 2) a large

345   fraction of the ULVOC/ELVOC from these precursors is produced by slower multi-generational

346   oxidation reactions (relative to the rapid autoxidation in the case of monoterpenes), while a rapid

347   formation of ULVOC/ELVOC is important to effectively compete with the strong condensation

348   loss in polluted areas. The net organic NPF rate in the real world is likely a combined effect of all

349   aforementioned precursors, with some precursors accelerating while others slowing down the NPF

350   rates given by our current model.

351   In addition to the NPF rate, the growth and removal of particles also affect the ambient particle

352   number. After ELVOC, most typically multifunctional hydroperoxides formed via autoxidation,

353   partition to the particle phase, they may undergo further particle-phase reactions, including

354   accretion reactions leading to oligomers and decomposition leading to shorter-chain compounds.[48,]

355   [49] Pospisilova et al.[48] suggested that the particle-phase reactions in α-pinene ozonolysis

356   experiments are likely dominated by the decomposition of reactive oxygen species, including

357   hydroperoxides. The lifetimes of these species against particle-phase reactions could span a large

358   range,[49] but are mostly about 30 to 150 min for α-pinene ozonolysis products.[48] The particle-phase

359   reactions result in continuous concentration and composition changes of SOA. The effect on NPF

360   remains unclear. The decomposition reaction might accelerate the evaporation of newly formed

361   particles and reduce the effective NPF rate; however, it is more likely that decomposition could

362   slow the growth rate of newly formed particles but not lead to complete evaporation. Even that is

363   uncertain. Decomposition products will not necessarily evaporate, and our results show that the

364   overall environment in the pollution plume is dominated by SOA formation and particle growth.

365   Thus, the particle-phase reactions are not likely to greatly change the NPF rate. Nevertheless,

366   future studies are needed to quantify the effect of particle-phase reactions on SOA and NPF in our

367   model. Furthermore, while our current model simulates the particle growth by condensation of

368   organics using an equilibrium partitioning method, recent studies showed that the growth and

369 evaporation kinetics can affect the size distribution evolution[20, 21] and thus needs to be considered

370 in future studies to better simulate the particle growth and size distribution in the pollution plumes.

371 For example, the diameter of the simulated peak number concentration grows slower than observed

372 as show in Fig. 3. The underestimate of particles in the range of 3–10 nm may also be partly

373 attributed to this issue (see more in Section 3 of SI). Finally, the chemical loss of organic particles

374 via photolysis[50] also needs to be accounted for to properly simulate the lifecycle and budget of

375 particles.

7. Discussion of the role of H_2SO_4 monomer and dimer

377 H_2SO_4 dimer is an important intermediate for many types of NPFs involving H_2SO_4. For acid-

378 base nucleation, such as the nucleation of H_2SO_4 with amine or NH_3, H_2SO_4 dimer plays a key

379 role in the nucleation process.[35, 51] For the nucleation of H_2SO_4 with organics, the main NPF

380 pathway in our region of interest, the situation is more complex. According to the mass defect

381 diagrams for negatively charged clusters during NPF experiments involving H_2SO_4 and organics

382 at the CLOUD chamber (Fig. 2a of Riccobono et al.[2] and Fig. 1c of Schobesberger et al.[52]), there

383 are many clusters of H_2SO_4 dimer with organics but there are even more clusters of H_2SO_4

384 monomer with organics. This indicates that the H_2SO_4 dimer is likely to play a certain but not the

385 most important role in the nucleation of H_2SO_4 with organics.

386   **Figures and Tables**

387
388   **Figure S1.** Comparison of Radical 2D-VBS simulated HOM yields and SOA concentrations with
389   smog-chamber and flow-tube experiments: (a) HOM molar yields from α-pinene + O_3, (b) HOM
390   molar yields from α-pinene + OH, and (c) SOA concentrations. The simulation results are obtained
391   with the final Radical 2D-VBS parameters used in our 3-D simulations. The measurements of α-
392   pinene + O_3 HOM molar yields are from Kirkby et al.[3], Ehn et al.[53], Sarnela et al.[54], and Jokinen
393   et al.[6]; the measurements of α-pinene + OH HOM molar yields are from Kirkby et al.[3], Ehn et
394   al.[53], Jokinen et al.[6], and Berndt et al.[55]; and the measurements of SOA concentrations are from
395   Shilling et al.[56], Presto and Donahue[57], and Ng et al.[58]. In (a) and (b), each dot represents the
396   measured HOM yield for an experiment or the simulated HOM yield for a model run (see a list of
397   all model runs in Table S2 and S3 of Zhao et al.[5]). For some studies (Kirkby, Ehn, and Jokinen in
398   (a); Kirkby, Jokinen, and Berndt in (b)), we only show one dot for measurements because the
399   corresponding literature only reports the mean HOM yield for all experiments. The studies
400   highlighted with an underline are flow-tube experiments.
401

402
403   **Figure S2.** Number density per pg (10^{-12} g) of primary particle emissions, according to the size
404   distribution used in the base case of this study ("base" in the figure), a number of previous regional
405   modeling studies ("Matsui et al.", "Cui et al.", and "Luo and Yu"), and two sensitivity cases in
406   this study ("nonuc_emis*4" and "nonuc_emis_finer"). For the "nonuc_emis*4" case, the figure
407   shows the number density per 4 pg of primary particle emissions. The size distribution of "Matsui
408   et al." has been used in Matsui et al.[25]; "Cui et al." has been used in Cui et al.[26] and Lupascu et

409   al.[27]; "Luo and Yu" has been used in Luo and Yu[28], Yu et al.[59], Chen et al.[60], and Chen et al.[29].
410   Note that in the base case and the two sensitivity cases ("nonuc_emis*4" and "nonuc_emis_finer"),
411   we assume the mass fraction of Aitken-mode particles to be 30% (cf. the baseline estimate of 10%
412   in Elleman and Covert[61]) for non-industrial urban sources in Manaus, which represents an urban
413   environment with a relatively high contribution from transportation emissions.
414

415
416   **Figure S3.** Comparison of simulated particle number concentrations (> 10 nm) averaged during
417   March 6–15, 2016 with surface observations at the T1 site. The number concentrations are
418   normalized to STP. The definitions of the model scenarios are summarized in Table S2.
419

420
421   **Figure S4.** Comparison of simulated particle number size distribution with surface observations
422   at the T1 site during March 6–15, 2016. The particle size distributions are normalized to STP. The
423   definitions of the model scenarios are provided in the main text and Table S2.
424

425
426 **Figure S5.** Comparison of simulated H_2SO_4 concentrations simulated by the base case
427 ("inorg+org_R2D-VBS") with surface observations at the T3 site. The concentrations are
428 normalized to STP.

429
430 **Figure S6.** NPF rates from seven pathways and the total NPF rate at a diameter of 1.7 nm ($J_{1.7}$) on the 2-km high vertical cross section
431 defined in Fig. 4, simulated by the base case ("inorg+org_R2D-VBS"). The results are averaged during the simulation period of this
432 study.

433
434 **Figure S7.** Spatial distribution of the contribution of different NPF pathways. (a) NPF rates from seven pathways and the total NPF rate
435 at a diameter of 1.7 nm ($J_{1.7}$) vertically averaged below 2 km, simulated by the base case ("inorg+org_R2D-VBS"). (b) The relative
436 contribution of the pure-organic ion-induced and organic+H_2SO_4 pathways to total NPF rate. The results are averaged during the
437 simulation period of this study.

438
439 **Figure S8.** The same as Fig. 2 but for the "nonuc" scenario and two sensitivity scenarios perturbing
440 the emission inventory. The definitions of the model scenarios are summarized in Table S2.
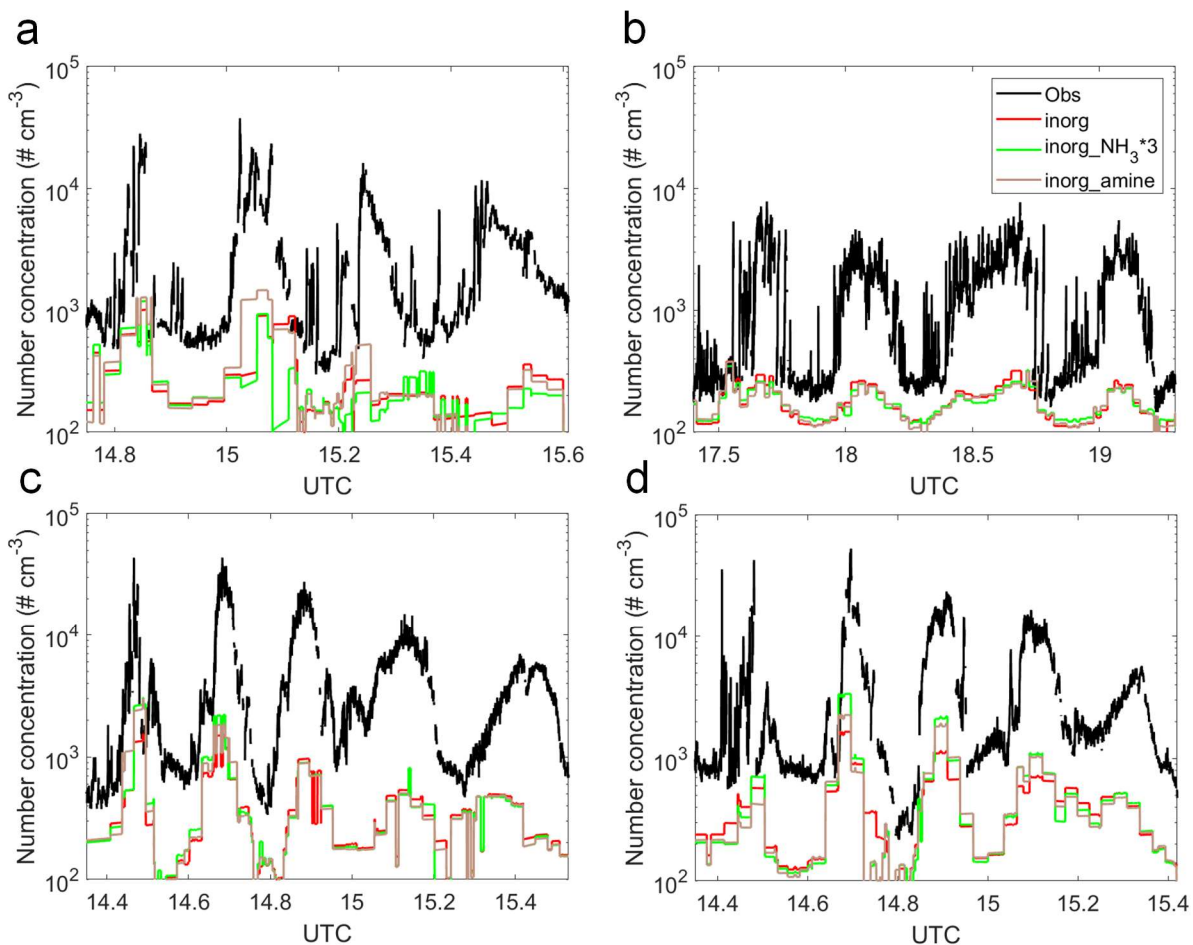

441
442 **Figure S9.** The same as Fig. 2 but for the "inorg" scenario, a sensitivity scenario perturbing NH_3
443 concentration, and a sensitivity scenario adding an NPF pathway involving H_2SO_4 and amines.
444 The definitions of the model scenarios are summarized in Table S2.

445
446 **Figure S10.** The same as Fig. 2 but for the base case (i.e., inorg+org_R2D-VBS) and two
447 sensitivity scenarios with different treatments of the formation chemistry of the organics that drive
448 NPF. The definitions of the model scenarios are summarized in Table S2.

Figure S11. Comparison of simulated particle number concentration in the range of 3–10 nm with G-1 aircraft measurements. (a) March 11, (b) March 12, (c) March 13, and (d) March 14, 2014. The particle number concentrations are normalized to STP. The definitions of the model scenarios are provided in the main text and Table S2.

Figure S12. The fractional contribution of NPF within the modeling domain to particle number concentrations on a 2-km high vertical cross section which extends westward from Manaus to 200 km downwind, simulated by (a) the base case, i.e., "inorg+org_R2D-VBS", (b) the scenario of "slow growth", and (c) the scenario of "slow growth below 10 nm". The position of the cross section is marked with a white arrow in Fig. 4d. The results are averaged during the simulation period of this study (March 6–15, 2014).
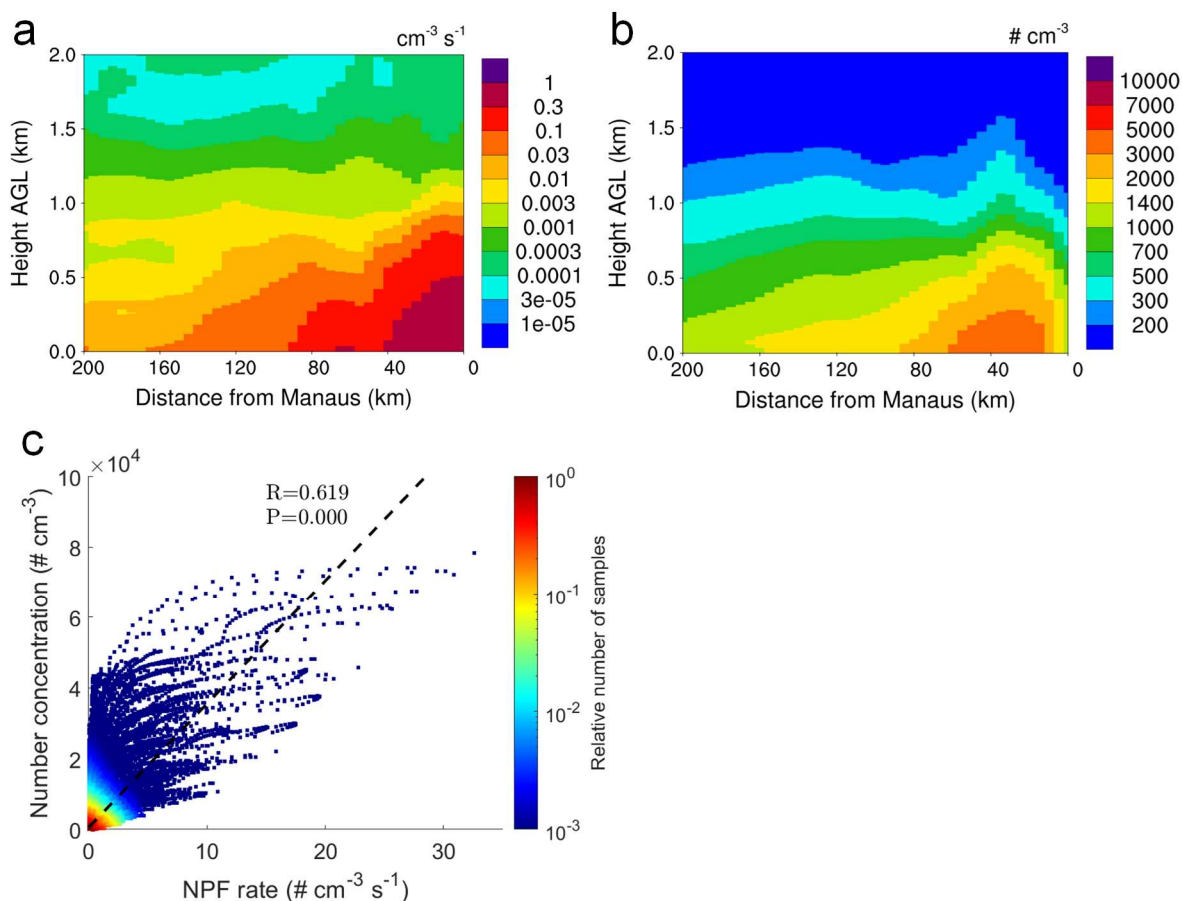

461
462 **Figure S13.** Relationships between NPF rate and increased particle number concentration due to
463 NPF. (a) NPF rate on a 2-km high vertical cross section which extends westward from Manaus to
464 200 km downwind. (b) Increased particle number concentration due to NPF on the cross section,
465 which is quantified using the difference between the base case ("inorg+org_R2D-VBS") and the
466 scenario without NPF ("nonuc"). The data in (a) and (b) are averaged during the simulation period
467 of this study (March 6–15, 2014). (c) Scattering plot of hourly average NPF rate vs. increased
468 particle number concentration due to NPF on the cross section during the simulation period. The
469 position of the cross section is marked with a white arrow in Fig. 4d.

470   **Table S1.** Parameters in the NPF model.

Parameter	Value	Parameter	Value
$p_{b,n}$	3.95451	$p_{b,i}$	3.373738
$u_{b,n}$	9.702973	$u_{b,i}$	−11.48166
$v_{b,n}$	12.62259	$v_{b,i}$	25.49469
$w_{b,n}$	−0.007066146	$w_{b,i}$	0.1810722
$p_{t,n}$	2.891024	$p_{t,i}$	3.138719
$u_{t,n}$	182.4495	$u_{t,i}$	−23.8002
$v_{t,n}$	1.203451	$v_{t,i}$	37.03029
$w_{t,n}$	−4.188065	$w_{t,i}$	0.227413
$p_{A,n}$	8.003471	$p_{A,i}$	3.071246
a_n	1.5703478×10^{-6}	a_i	0.0048314
k_{SA-Org}	3.27×10^{-21}	a_1	0.0400097
a_2	1.84826	a_3	0.00136641
a_4	1.56588	a_5	0.186303
$k_{SA-Amine\text{-}1}$	2.08×10^{-25}	$k_{SA-Amine\text{-}2}$	1.93×10^{-28}

471   Note: Full numerical precision is needed. The units of $[ULVOC_{O:C>0.4}]$ are 10^7 cm^{-3}. $[H_2SO_4]$ has units 10^6 cm^{-3} in
472   J_{SA} and $J_{SA,NH3}$, and cm^{-3} in J_{SA-org} and $J_{SA-Amine}$. $[NH_3]$ has units 10^6 cm^{-3} and $[DMA]$ has units cm^{-3}. The
473   ion and $[ELVOC_{O:C>0.4}]$ concentrations have units cm^{-3}.
474

475   **Table S2.** Summary of model scenarios developed in this study.

Scenario	Description
Main scenarios	
nonuc	A simulation without NPF.
inorg	A simulation with only inorganic NPF included.
inorg+org_R2D-VBS	A simulation with both inorganic and organic NPF included, and the organics that nucleate are simulated employing the updated Radical 2D-VBS that uses two types of autoxidizable RO_2 with faster and slower autoxidation rates. This is considered as the base-case scenario and is used in most analyses of the present study.
Sensitivity scenarios	
nonuc_emis*4	Based on "nonuc", this scenario increases primary particle emissions by a factor of 4.
nonuc_emis_finer	Based on "nonuc", this scenario reduces the Aitken-mode median diameter of primary particle emissions from urban sources from 25 nm to 12 nm.
inorg_NH$_3$*3	The same as "inorg" except that the NH_3 concentrations across the domain are increased by a factor of 3.
inorg_amine	The same as "inorg" except that an NPF pathway involving H_2SO_4 and amines is incorporated.

inorg+org_simple	The same as "inorg+org_R2D-VBS" except that the organics that nucleate are assumed to be a fixed fraction of all monoterpene oxidation products.
inorg+org_R2D-VBS_uniauto	The same as "inorg+org_R2D-VBS" except that a uniform autoxidation rate is used for all RO_2 of the same generation.

476

477 **Table S3.** Statistics (mean ± standard deviation) of major meteorological variables within the
478 modeling domain during the main simulation period in March 2014 and supplementary simulation
479 period in March 2016.

	March 6–15, 2014		March 6–15, 2016	
	surface	500 m	surface	500 m
