Characterizations

The resulting samples were characterized using SEM (Zeiss, 5.0–20.0 kV), XRD (AXIS Ultra) and XPS (Bruker D8 diffractometer). The Raman spectroscopy was performed with the LabRAM HR Evolution Raman microscopes (HORIBA), and an Argon laser (λ = 514 nm, National Laser Model 800AL) was used as the excitation line. The N_2 adsorption-desorption isotherms were measured by a Micromeritics ASAP 2020 Brunauer-Emmett-Teller (BET) analyzer. The STEM, STEM-EDS and EELS studies were conducted using a JEOL ARM200F atomic resolution analytical electron microscope equipped with a cold field-emission gun and a new ASCOR 5th order aberration corrector, an Oxford X-max 100TLE solid state detector and a Gatan Quantum ER spectrometer. The X-ray absorption find structure spectra (Ti K-edge) were collected at 1W1B station in Beijing Synchrotron Radiation Facility (BSRF). The storage rings of BSRF were operated at 2.5 GeV with a maximum current of 250 mA. Using Si (111) double-crystal monochromator, the data collection was carried out in transmission mode using ionization chamber. All spectra were collected in ambient conditions.

Electrochemical characterization and calculations

All the SCs were characterized by an electrochemical workstation (Solartron 1470E) at room temperature. The CV and GCD measurements were conducted at room temperature to evaluate the electrochemical performance of SCs. The $C_{vol\text{-}electrode}$ of MXene and BP@MXene film electrodes were calculated by their CV curves on the following equation: $C_{vol-electrode} = \frac{1}{\Delta Vs}\int_0^{\Delta V}j\mathrm{d}V$, where j is the discharging current density (A cm^{-3}), $\int_0^{\Delta V}jdV$ is the integrated area of CV curve, ΔV is the potential window (V), and s is the scan rate (V s^{-1}). The $C_{vol\text{-}electrode}$ of MXene and BP@MXene film electrodes were calculated by their GCD curves on the following equation: $C_{vol-electrode} = -\frac{I\,\Delta t}{V\Delta V}$, where I is the discharging current (A), $\Delta V/\Delta t$ is the slope after drop at the beginning of each discharging curve, V is the geometrical volume of film electrodes. The volumetric energy density

against two electrodes ($E_{vol-electrode}$) in device was calculated using the following formula: $E_{vol-electrode}$ = $C_{vol-electrode}U^2/8$, where U is the operating voltage. The volumetric energy density against the entire SC stack ($E_{vol-stack}$) was obtained based on the following formula: $E_{vol-stack} = E_{vol-electrode} \times f_{electrode}$, where $f_{electrode}$ is volume fraction of the electrode materials. The entire device stack includes two electrodes with electrolytes, two current collectors (Pt foils), one separator and parafilm packaging. The thickness and areal mass of one membrane separator with electrolyte are ~25 μm and ~ 3 mg cm^{-2}; the thickness and areal mass of one Pt current collector are ~20 μm and ~ 5.8 mg cm^{-2}; the thickness and areal mass of total wrapped parafilm package are ~100 μm and ~ 15 mg cm^{-2}; the thickness and areal mass of one thick electrode (15 mg cm^{-2} per film electrode) with electrolyte are ~225 μm and ~ 25 mg cm^{-2}. The $E_{vol-stack}$ were normalized by the total volume of the entire device with only consideration of electrode area, which is similar to the approach used in recent reports.[1,2] The various power densities of the device (P) were calculated from the following formula: $P = E/\Delta t$, where Δt is the discharge time.

Computational details

In this paper, the DMol3 module based on DFT using a numerical radial function was employed to view EMIM$^+$/TFSI$^-$ ions performance of MXene and BP@MXene capacitive energy storage.[3] The generalized gradient approximation (GGA) with Perdew–Burke–Ernzerhof (PBE) function exchange–correlation potential was employed for the geometry optimization.[4] The basis set adopted the double numerical basis plus polarization function (DNP).[5] The special k-point sampling scheme of Monkhorst-Pack was used for approximating the Brillouin zone integrations,[6,7] and $1 \times 2 \times 1$ k-point grids were used. The spin-unrestricted and auto multiplicity state were also employed to calculate the total electron densities. Geometrical optimization was made, and convergence was assumed when the convergence tolerance of energy, maximum force and maximum displacement were less than 1.0×10^{-5} Ha, 0.002 Ha/Å and 0.005 Å, respectively. For achieving high quality

results, the real space global orbital cutoff radius was set as 5.2 Å and the smearing of orbital occupancy was 0.005 Ha.

Models for EMIM$^+$/TFSI$^-$ ions adsorbed on activation sites constructed to confirm the most stable adsorption models. After geometric optimization, the adsorption energies (E_G) of these molecules were calculated through the following equation:

$$E_G = E_{*A} - (E_* + E_A)$$

Where, E_{*A} and E_* are the energies of MXene or BP@MXene with and without adsorption molecules, respectively. E_A is the energy of a free molecule of the adsorption molecule. From this definition, a negative value of E_G indicates that the formation process is exothermic, and a more negative value corresponds to a more readily and preferred generation scenario.

	Ti-Ti	1.4	3.42	6.5	2.7	
MXene	Ti-O(C)	3.4	2.06	7.0	3.4	
	Ti-Ti	6.0	2.99	6.9	8.0	0.6
	Ti-Ti	1.4	3.48	6.5	2.7	

[a]N: coordination numbers; [b]R: bond distance; [c]σ^2: Debye-Waller factors; [d]ΔE_0: the inner potential correction. R factor: goodness of fit. S02 for Ti-N/Ti-Ti were set as 0.85/0.9, which were obtained from the experimental EXAFS fit by fixing CN as the known crystallographic value and was fixed to all the samples.[8-10]

Notes: Error bounds (accuracies) that characterize the structural parameters obtained by EXAFS spectroscopy were estimated as N ± 20%、 σ^2 ± 20%; R ± 0.03 Å.

The acquired EXAFS data was processed according to the standard procedures using the ATHENA module implemented in the IFEFFIT software packages. The k^3-weighted EXAFS spectra were obtained by subtracting the post-edge background from the overall absorption and then normalizing with respect to the edge-jump step. Subsequently, k^3-weighted χ(k) data of Ti-K-edge were Fourier transformed to real (R) space using a hanning windows (dk = 1.0 Å^{-1}) to separate the EXAFS contributions from different coordination shells. To obtain the quantitative structural

parameters around central atoms, least-squares curve parameter fitting was performed using the ARTEMIS module of IFEFFIT software packages.

Figure S16. CV curves of the BP@MXene film electrode in three-electrode electrochemical cell at various scan rates ranging from 2.0 to 1000 mV s^{-1} in 1.0 M Na$_2$SO$_4$ electrolyte.

In 1.0 M Na$_2$SO$_4$ electrolyte at neutral pH, the free-standing BP@MXene film was evaluated as a working electrode in a three-electrode electrochemical cell (Ag/AgCl as the reference electrode; Pt foil as counter electrode), which was saturated by N$_2$ before testing. As show in Figure S16, the stable operation potential window of the BP@MXene film electrode can be observed between −0.8 and 0.0 V, which is consistent with the previously reported results of MXene-based electrodes texted in neutral electrolytes. Moreover, all CV curves from the scan rates of 2.0–1000 mV s^{-1} present nearly rectangular shapes, indicating the capacitive behaviour and the outstanding reversibility of the BP@MXene film electrode.
Figure S17. (a) EIS plots and (b) the corresponding equivalent circuit of MXene and BP@MXene-SCs in 1M Na_2SO_4 electrolyte.

As shown in Figure S17(b), the impedance data were analyzed by fitting with an equivalent circuit consisting of the series resistance (R_s), charge transfer resistance (R_{ct}), double layer capacitance (C_{DL}) and Warburg impedance (Z_W). At high frequency range, the value of the intercept at the real axis is used to estimate the R_S of the electrodes, which is the combination of the ionic resistance of the electrolyte and the resistance of the electrode material itself. The semicircle diameter in the plot corresponds to the R_{ct}, also called Faraday resistance, corresponding to the total resistance at the interface between the electrode and the electrolyte. In addition, R_{ESR} is the equivalent series resistance of the device, which was calculated *via* dividing the voltage drop (U_{drop}) at the beginning of the discharge by the applied constant current (I) using the formula: $R_{ESR} = U_{drop}/2I$. It should be noted that the R_{ESR} of an SC is related to both R_S and R_{CT} in the electrodes. Figure S17 (a) and Table S4 present the R_s values of the BP@MXene-SC and MXene-SC in 1.0 M Na_2SO_4 electrolyte are 2.94 Ω and 2.28 Ω, showing almost no variation in the total resistance between BP@MXene and MXene films. However, the R_{ct} of the SCs decreases from 5.35 Ω to 2.92 Ω after the introduction of BP nanoparticles onto the surface of MXene flakes, demonstrating that BP nanopartilces can not only serve as effective nanospacers to expand the nanofluidic channels of MXene multilayers in the compact film electrode, thereby accelerating electrolyte ion transportation,

but also effectively isolate the aggregation and face-to-face self-restacking of MXene flakes during film electrode fabrication processes. Furthermore, an R_{ESR} of 5.86 Ω and 7.63 Ω was obtained for the BP@MXene-SC and the MXene-SC respectively.

Table S4. Fitting results for EIS of the two SCs in 1.0 M Na_2SO_4 electrolyte.

Devices	R_s (Ω)	R_{ct} (Ω)	R_{ESR}	C_{DL}	Z_W
BP@MXene-SC	2.94	2.92	5.86	0.76321	0.68479
MXene-SC	2.28	5.35	7.63	0.78468	0.65347
Figure S18. Linear relations between Z_w and $\omega^{-1/2}$ of (a) BP@MXene-SC and (b) MXene-SC in 1.0 M Na_2SO_4 electrolyte.

To understand the kinetics of electrolyte diffusion within BP@MXene film electrode, the depressed semicircle at medium frequencies presenting the ion-diffusion resistance was fitted *via* following equation,

$$Z_w = R_s + R_{ct} + \sigma\omega^{-1/2}$$

, where σ is the Warburg factor (the diffusion coefficient of Na^+ ions [D_{Na+}], which is inversely proportional to σ^{-2} [$D_{Na+} \propto 1/\sigma^2$]), and ω is the frequency.

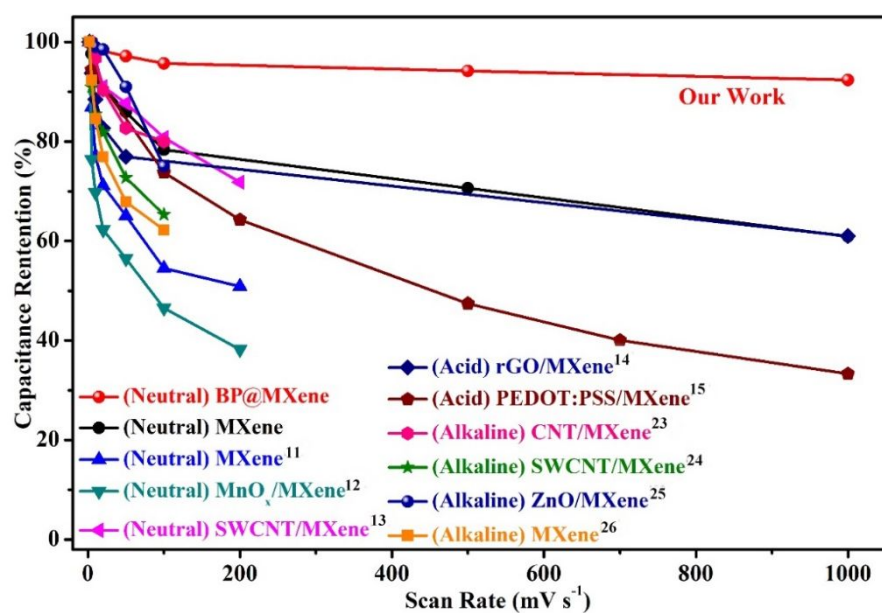

Figure S23. Comparison of rate performance of BP@MXene-SC with those of reported MXene-based electrodes.[11-15, 23-26]
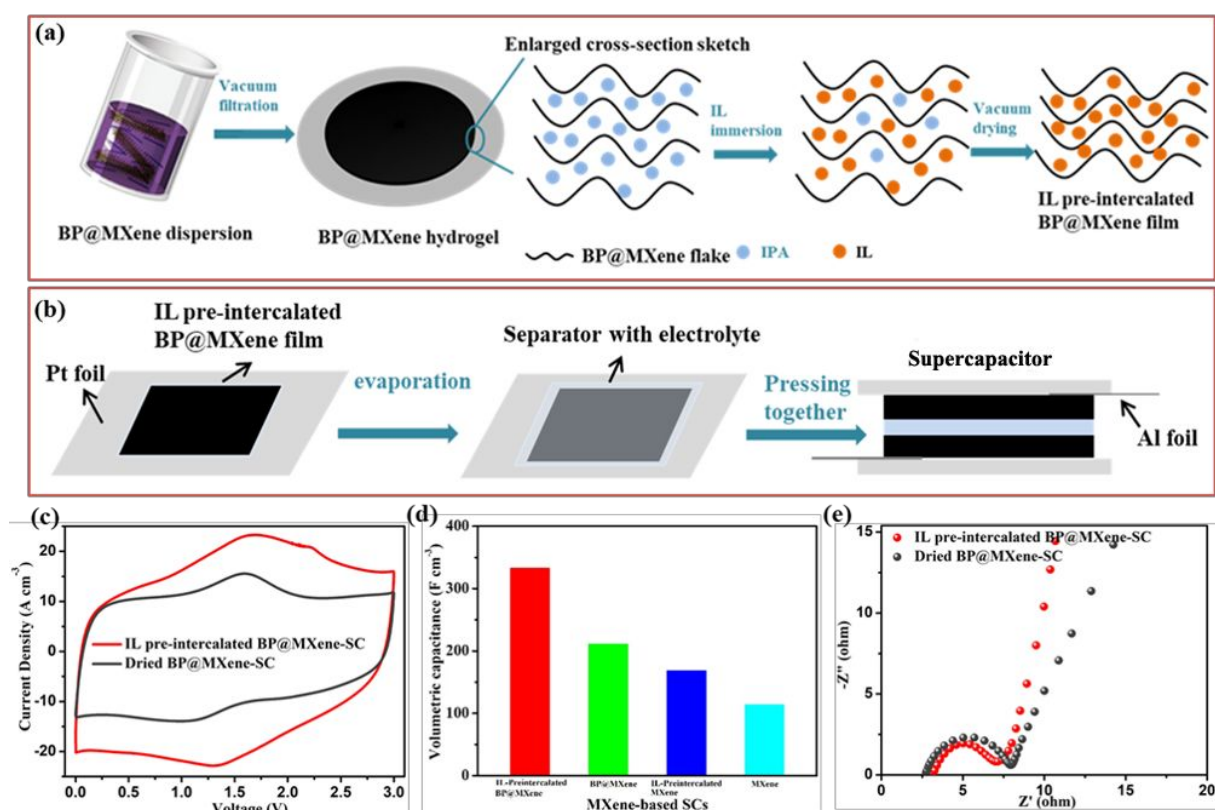

Figure S24. Schematic illustration of (a) preparing IL pre-intercalated BP@MXene film and (b) fabricating symmetric supercapacitor based on IL pre-intercalated BP@MXene film. Comparison of (c) CV curves tested at 50 mV s^{-1}, (d) volumetric capacitances and (d) EIS plots of IL pre-intercalated BP@MXene and MXene-SCs.

Indeed, various ionic liquids (ILs) have been recently employed for MXene-based SCs, which allow for the expansion of their maximum device voltage (up to ~3.0–3.5 V), but the insufficient accessibility to the large ions of ILs impedes the full utilization of the surface area thus leading to poor capacitance and rate capability. In this regard, we developed a reported strategy to obtain IL pre-intercalated BP@MXene compact film with a high ion-accessible surface area and low ion transport resistance (Figure S24a).[27] To investigate the importance of IL pre-intercalation into the BP@MXene film for the performance enhancement of SCs, we assembled two different kinds of SCs based on IL pre-intercalated BP@MXene film and dried BP@MXene film (drying at 120 °C for 24 h

under vacuum, Figure 24b-d), respectively, and the electrochemical performance of as-assembled SCs were tested in neat 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (EMIMTFSI) electrolyte with a working voltage of 3.0 V. Note that the EMIMTFSI IL is primarily chosen in our work because of its high viscosity and high specific conductivity. Figure S242(c) shows the CV curves of both two SCs at a scan rate of 50 mV s^{-1}, in which the IL pre-intercalated BP@MXene film delivers obviously higher integration area than dried BP@MXene, indicative of the improved C_{vol} of IL pre-intercalated BP@MXene-SC. As a result, the IL pre-intercalated BP@MXene film delivers a C_v of 332.6 F cm^{-3} (Figure 24d), which is 1.58 times higher than that of dried BP@MXene film (210.8 F cm^{-3}). It should be noted that the redox peaks in CV curves resulted from the insertion and extraction of EMIM$^+$ cations during charge and discharge processes. Furthermore, the electrochemical impedance spectrum (EIS) of IL pre-intercalated BP@MXene-SC presents a lower charge transfer resistance (R_{ct}) in the high-frequency region and a larger slope in the low-frequency region (Figure S24e), in comparison with that of dried BP@MXene-SC, reflecting a faster ion dynamics and more efficient electrolyte diffusion within the IL pre-intercalated BP@MXene film electrode. These above-mentioned results indicate that the pre-intercalation of the IL electrolyte into BP@MXene film with expanded interlayer spacing can intensively accommodate more available ions, providing a high ion-accessible surface area and low ion transport resistance, and thus dramatically increase the overall electrochemical performance of BP@MXene active materials.'
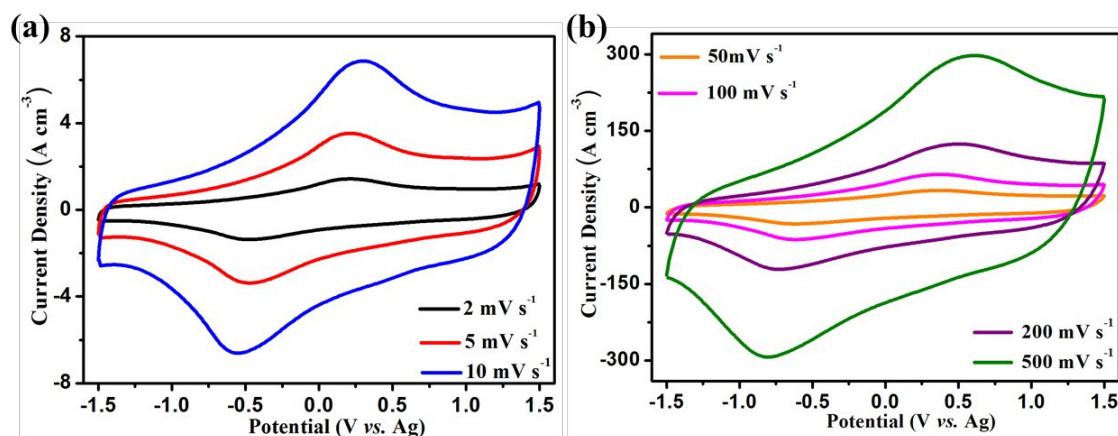

Figure S25. CV curves of the IL pre-intercalated BP@MXene film electrode in a three-electrode Swagelok cell at various scan rates ranging from 2.0 to 500 mV s^{-1} in neat EMIMTFSI IL electrolyte.

The IL pre-intercalated BP@MXene film was evaluated as the working electrode in a three-electrode Swagelok symmetric cell (an Ag wire as quasi-reference electrode and a commercial activated carbon as counter electrode) in neat EMIMTFSI IL electrolyte at room temperature. As shown in Figure S25, the symmetric CV shapes indicate a capacitive behavior within a potential window from –1.5 V to 1.5 V *vs.* Ag. The obvious redox peaks have resulted from the insertion and extraction of EMIM$^+$ cations and/or TFSI$^-$ anions under negative, and positive polarizations can be observed in all CV curves. Moreover, all CV curves from the scan rates of 2.0–500 mV s^{-1} maintain similar shapes with a slight shift in the anodic and cathodic peaks, demonstrating an excellent capacitive behavior.
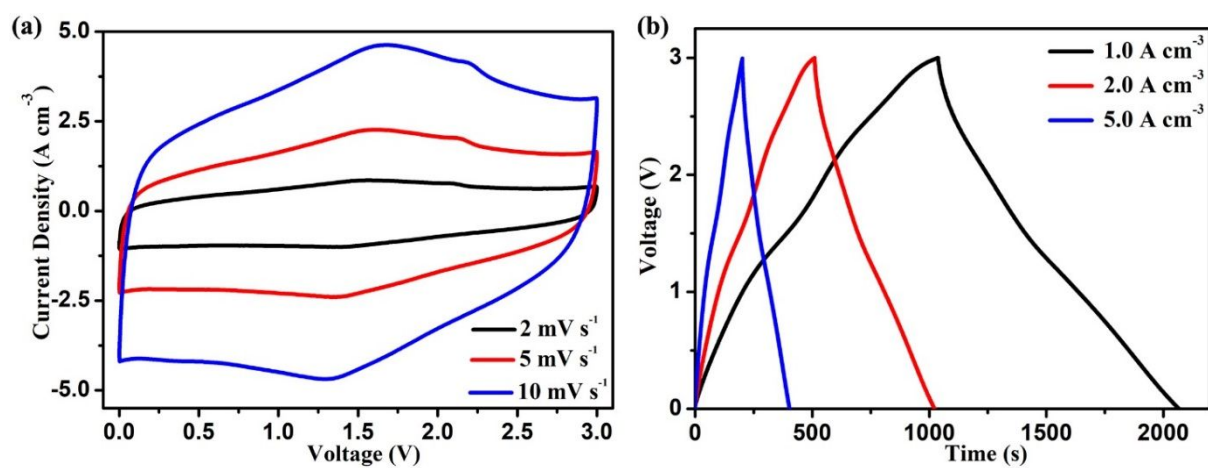

Figure S26. (a) CV curves under different scan rates. (e) GCD curves of as-assembled BP@MXene-SC in EMIMTFSI.
