## Mössbauer analysis of the $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ complex.

An independent sample of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right](\mathrm{OTf})_{2}$ was prepared by adding 1 equivalent of peracetic acid to a 1 mM acetonitrile solution of $\left[\mathrm{L}^{57} \mathrm{Fe}^{\mathrm{II}}(\mathrm{NCMe})\right](\mathrm{OTf})_{2}$. The zero field Mössbauer spectrum of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ is shown Figure S1A. The red solid line represents a spectral simulation obtained by adding two quadrupole doublets with $\Delta \mathrm{E}_{\mathrm{Q} 1}=0.95(3) \mathrm{mm} \cdot \mathrm{s}^{-1}, \delta_{1}=0.00(2) \mathrm{mm} \cdot \mathrm{s}^{-1}($ doublet $1, \approx 50 \%)$, and $\Delta \mathrm{E}_{\mathrm{Q} 2}=$ $1.49(2) \mathrm{mm} \cdot \mathrm{s}^{-1}, \delta_{2}=0.45(1) \mathrm{mm} \cdot \mathrm{s}^{-1}$ (doublet $2, \approx 46 \%$ ). The doublet 2 has an isomer shift typical for a high-spin $\mathrm{Fe}^{\mathrm{III}}$ species. In applied magnetic fields, this species exhibits diamagnetic behavior and can be described as a diiron(III) complex (diiron(III) is often the thermodynamic sink in this chemistry). After subtraction of the doublet 2 (Figure $\mathrm{S} 1 \mathrm{~B})$, doublet 1 is obtained with parameters typical of $\mathrm{Fe}^{\mathrm{IV}}(\mathrm{O})$ complexes. ${ }^{1}$ The Mössbauer spectra of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ were also recorded at 4.2 K in parallel applied fields up to 8.0 T , as well as 8.0 T spectra at 30 K and 100 K (Figures S2 and S3).
We have simulated the spectra of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ using the $\mathrm{S}=1$ spin Hamiltonian:

$$
\left.\begin{array}{l}
\hat{\mathcal{H}}=\mathrm{D}\left(\hat{\mathrm{~S}}_{\mathrm{z}}^{2}-2 / 3\right)+\mathrm{E}\left(\hat{\mathrm{~S}}_{\mathrm{x}}^{2}-\hat{\mathrm{S}}_{\mathrm{y}}^{2}\right)+2 \beta \mathbf{B} \cdot \hat{\mathbf{S}}+\hat{\mathbf{S}} \cdot \mathbf{A} \cdot \hat{\mathbf{I}}-\mathrm{g}_{\mathrm{n}} \beta_{\mathrm{n}} \mathbf{B} \cdot \hat{\mathbf{I}}+\hat{\mathcal{H}}_{\mathrm{Q}} \\
\hat{\mathcal{H}}_{\mathrm{Q}}=\left(\frac{\mathrm{eQV}}{\mathrm{zz}}\right. \\
12
\end{array}\right)\left(3 \hat{\mathrm{I}}_{\mathrm{z}}^{2}-15 / 4+\eta\left(\hat{\mathrm{I}}_{\mathrm{x}}^{2}-\hat{\mathrm{I}}_{\mathrm{y}}^{2}\right)\right) .
$$

The parameters obtained are listed in Table S1.

Figure S1. (A) 4.2 K Mossbauer spectrum of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ generated by adding 1 equivalent of peracetic acid to $\left[\mathrm{L}^{57} \mathrm{Fe}^{\mathrm{II}}(\mathrm{NCMe})\right](\mathrm{OTf})_{2}$ in $\mathrm{MeCN}(\mathrm{B})$ spectrum obtained after subtraction of $46 \%$ of a diferric component from the raw data. The solid line in (A) is a spectra simulation containing $\approx 50 \%$ of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ and $\approx 46 \%$ of the diferric species. The red solid line in (B) is a spectral simulation for the $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ component, using $\Delta \mathrm{E}_{\mathrm{Q} 1}=0.95 \mathrm{~mm} / \mathrm{s}$ and $\delta_{1}=0.00 \mathrm{~mm} / \mathrm{s}$.

Figure S2. 4.2 K Mössbauer spectrum of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ generated by adding 1 equivalent of peracetic acid to $\left[\mathrm{L}^{57} \mathrm{Fe}^{\mathrm{II}}(\mathrm{NCMe})\right](\mathrm{OTf})_{2}$ in MeCN , recorded in an 8.0 T field applied parallel to the observed $\gamma$ radiation. The red line is a spectral simulation of high-spin $\mathrm{Fe}^{3+}$ contaminants representing $\approx 8 \%$ of the iron in the sample.

Figure S3. Mössbauer spectra of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ generated by adding 1 equivalent of peracetic acid to $\left[\mathrm{L}^{57} \mathrm{Fe}^{\mathrm{II}}(\mathrm{NCMe})\right](\mathrm{OTf})_{2}$ in MeCN . The spectra were recorded in 4.0 T (A) and $8.0 \mathrm{~T}(\mathrm{~B}, \mathrm{C}, \mathrm{D})$ applied parallel to the $\gamma$ ray at temperatures as indicated. The spectra were obtained after subtraction of the $46 \%$ of the diiron(III) species. The red solid lines are spectral simulations to an $\mathrm{S}=1$ spin Hamiltonian using the parameters listed in Table S1.

## DFT-analysis of the $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ complex.

The density functional theory (DFT) calculations for $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ was performed using Becke's three parameter hybrid functional (B3PLY) and basis set 6311G provided by Gaussian'03 software package. ${ }^{2}$ The quadrupole splitting $\Delta \mathrm{E}_{\mathrm{Q}}$ was calculated using the properties keyword of the Gaussian code using $\alpha\left({ }^{57} \mathrm{Fe}\right)=0.17$ barn. The ${ }^{57} \mathrm{Fe}$ isomer shift $\delta$ was evaluated from the DFT charge density at the Fe nucleus using the calibration given by Vrajmasu et al. ${ }^{3}$ The SCF procedure and geometry optimization were terminated upon reaching the default convergence criteria (Figure S 4 ). The calculated $\mathrm{Fe}-\mathrm{O}$ bond distance is $1.65 \AA$, which agrees with the $\mathrm{Fe}-\mathrm{O}$ bond distances for other $\mathrm{S}=1 \mathrm{Fe}^{\mathrm{IV}}(\mathrm{O})$ complexes. ${ }^{1,4}$ The DFT-calculated Mössbauer parameters agree quite well with the experimental data (Table S1).

We also optimized the geometry of the structure of $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ where the oxo and MeCN groups have been exchanged (not shown), leading to a structure with the oxo group trans to a $\mathrm{N}_{\mathrm{py}}$ and the MeCN group trans to $\mathrm{N}_{\mathrm{am}}$. This conformation is $2400 \mathrm{~cm}^{-1}$ higher in energy.

Figure S4. Geometry optimized structure of the $\left[\mathrm{LFe}^{\mathrm{IV}}(\mathrm{O})(\mathrm{NCMe})\right]^{2+}$ complex. Hydrogen atoms have been omitted for clarity.

## Supplemental information on the Mössbauer analysis of complex 2.

The spectrum in Figure S5 contains two quadrupole doublets assigned to $\mathbf{2}$ and diferric components ( $\approx 35 \%$ of total Fe ). As only 0.8 equiv. peroxide were used, it is reasonable to assume that ca. $20 \%$ of the Fe in the sample belongs to $\mathbf{1}$. Roughly $10 \%$ of the absorption may be attributable to diferric decay product(s) and a starting material contaminant, and since these diferric species yield spectra quite similar to those of $\mathbf{1}$, we have represented the spectra of all diferric species, for lack of better information, by the spectrum of $\mathbf{1} . \mathrm{Ca} .5 \%$ of the iron in the sample belonged to green intermediate $\mathbf{4}$; its contribution was determined by EPR and by comparing Mössbauer spectra recorded at 4.2 K and 100 K . Throughout the project we have searched for a method, other than Mössbauer spectroscopy, to determine the fraction of $\mathbf{2}$ in a sample, and we found that the amount of red intermediate $\mathbf{3}$ obtained by protonation correlates very well with the

Mössbauer analysis. For instance, for an aliquot of the present Mössbauer sample $65 \%$ of the starting material, upon protonation, was converted into $\mathbf{3}$. We have produced one sample containing ca. $\mathbf{7 5 \%}$ of $\mathbf{2}$; however, for this sample ca. $10 \%$ of the iron belonged to a heterogeneous mixture of paramagnetic high-spin ferric contaminants displaying spectral features that were difficult to recognize in high-field spectra.

Figure S5. Mössbauer spectrum (A) of 2 in 1:1 mixture of acetonitrile/butyronitrile, recorded at 4.2 K in zero field. The solid line is a spectral simulation of the diferric contaminants. (B) Spectrum of 2 obtained by subtracting the contaminants of (A) from the raw data.

We have measured the spectra of $\mathbf{2}$ for $\mathrm{B}=0$ up to 190 K and found that the intensity of doublet a (relative to $\mathbf{b}$ ) and also its quadrupole splitting decrease with increasing temperature (Figure S6), and these changes are accompanied by a broadening of the lines, caused by dynamic effects perhaps involving the OH group of site $\mathbf{a}$. As we were writing up this manuscript, we prepared a sample of $\mathbf{2}$ using $\mathrm{D}_{2} \mathrm{O}_{2}$; see Material and Methods. An initial Mössbauer study of that sample gave a very interesting result, namely that the recoilless fraction (Debye-Waller factor), f, of site a declines substantially faster above 100 K than the f -value of site $\mathbf{b} .{ }^{5}$ The decline in f is illustrated in Figure S 6 which shows
a superposition of 4.2 K and 140 K spectra of the $\mathrm{D}_{2} \mathrm{O}_{2}$ sample. At 140 K we find for doublets $\mathbf{a}$ and $\mathbf{b}$ an intensity ratio $[\mathbf{b}] /[\mathbf{a}]=1.4$ rather than $1: 1$ as observed at 4.2 K . We have reported a similar, but less dramatic, phenomenon for the $\mathrm{Fe}^{2+}$ site of the P-cluster of nitrogenase. ${ }^{6}$ We will study the high-temperature behavior more thoroughly with both EXAFS and Mössbauer spectroscopy, and report the results elsewhere. Interestingly, the sample prepared with $\mathrm{D}_{2} \mathrm{O}_{2}$ did not suffer from line broadening above 100 K . Given that the high temperature spectra of the sample of Figures 2 and 3 consist of a superposition of at least seven quadrupole doublets with unknown high-temperature behavior, we are presently not able to properly decompose the spectra.

Figure S6. Comparison of the 4.2 K (black) and 140 K (red) spectra of a sample of 2 prepared with $\mathrm{D}_{2} \mathrm{O}_{2}$. $74 \%$ of the Fe in the sample belongs to 2 and ca. $25 \%$ to diferric species. At 4.2 K , doublet a (arrows) accounts for ca. $37 \%$ of the total absorption; this fraction declines to $28 \%$ of the total absorption at 140 K . The average recoilless fraction declines by a factor 2 between 4.2 K and 140 K ; the recoilless fraction of doublet a declines by nearly a factor 3 . Vertical scale refers to 4.2 K spectrum.

Figure S7. Representation of the coordinate frame $\{x, y, z\}$ of the $\mathrm{Fe}_{\mathrm{O}}$ site of 2 viewed from two perspectives; the z axis is along the $\mathrm{Fe}=\mathrm{O}$ bond and the x axis is along the $\mathrm{N}_{\text {trans }}--\mathrm{N}_{\text {trans }}$ direction on the $\mathrm{Fe}_{\mathrm{o}}$ site. Left: view from top along the x axis; right: view from the front of the molecule. Atom colors: blue, nitrogen; red, oxygen; grey, iron; white, hydrogen. Except for the coordinating atoms, the ligands have been omitted for clarity.

Figure S8. Representation of the experimental and DFT-calculated principal values of the EFG- (in mm/s), $\mathrm{A}_{\mathrm{SD}^{-}}$and $\mathrm{A}_{\text {total }}$-tensors (in T) (opt, method 1; prop, method 2) using the coordinate frame of the $\mathrm{Fe}_{\mathrm{O}}$ site, $\{\mathrm{x}, \mathrm{y}, \mathrm{z}\}$, as a reference, where the z axis is along the $\mathrm{Fe}_{\mathrm{O}}-\mathrm{O}_{\mathrm{T}}$ bond and the x axis is along the $\mathrm{N}_{\text {trans }}--\mathrm{N}_{\text {trans }}$ direction on the $\mathrm{Fe}_{\mathrm{O}}$ site. The principal axes of the EFG and $\mathrm{A}_{\mathrm{SD}}$ tensors at $\mathrm{Fe}_{\mathrm{OH}}$ are close to but do not coincide with the $\{\mathrm{x}, \mathrm{y}, \mathrm{z}\}$ axes. Atom colors: blue, nitrogen; red, oxygen; grey, iron; white, hydrogen.

Figure S9. Representation of the experimental and DFT-calculated principal values of the EFG- (in mm/s), $\mathrm{A}_{\mathrm{SD}}-$ and $\mathrm{A}_{\text {total }}$-tensors (in T) by (both opt and prop, method 1) using the coordinate frame of the $\mathrm{Fe}_{\mathrm{O}}$ site, $\{\mathrm{x}, \mathrm{y}, \mathrm{z}\}$, as a reference, where the z axis is along the $\mathrm{Fe}_{\mathrm{O}}-\mathrm{O}_{\mathrm{T}}$ bond and the x axis is along the $\mathrm{N}_{\text {trans }}--\mathrm{N}_{\text {trans }}$ direction on the $\mathrm{Fe}_{\mathrm{O}}$ site. The principal axes of the EFG and $\mathrm{A}_{\mathrm{SD}}$ tensors at $\mathrm{Fe}_{\mathrm{OH}}$ are close to but do not coincide with $\{x, y, z\}$ axes (see main text). Atom colors: blue, nitrogen; red, oxygen; grey, iron; white, hydrogen.

## Comments on DFT Calculations for Complex 2.

## Methods.

Density functional theory (DFT) calculations were performed for complex 2 and for the analog of complex 2 supported by a truncated version of the ligand, tris(pyridyl-2methyl)amine (TPA), where the substituents on the pyridyl rings have been replaced by H.

Method 1: calculations were performed with the Amsterdam Density Functional (ADF) 2008.01 software package ${ }^{7}$ on a cluster of 10 processors (Ace computers) using ADF basis set IV (triple- $\zeta$ with single polarization on the ligand atoms), an integration constant of 4.0, and the Vosko-Wilk-Nusair local density approximation ${ }^{8}$ with the nonlocal
gradient corrections of Becke ${ }^{9}$ and Perdew ${ }^{10}$ (BPVWN). The coordinates of the optimized geometry are reported in Table S12. A-tensor and electric field gradient calculations in ADF were performed using the ESR and QTENS commands, respectively. Spin-orbit contributions to the A-tensor were neglected. The EFG has been converted to energy units, using $\mathrm{Q}\left({ }^{57} \mathrm{Fe}\right)=0.17$ barn. Since the calculations employed basis sets with frozen cores, the resulting $\mathrm{A}_{\text {iso }}$ values (Fermi contact term) were meaningless; however, it was still possible to extract the spin-dipolar terms by subtraction of $\mathrm{A}_{\text {iso }}$ from the computed $\mathbf{A}$ tensor. Finally, since ADF assumed an effective spin of 2, the calculated values are divided by 2 to obtain the local A-values.

Method 2: calculations were performed using Becke's three parameter hybrid functional (B3LYP) ${ }^{11,12}$ and basis set $6-311 \mathrm{G}$ provided by Gaussian'03 software package ${ }^{2}$ on a cluster of 8 processors. ${ }^{13}$ The quadrupole splitting $\Delta \mathrm{E}_{\mathrm{Q}}$ was calculated using the properties keyword of the Gaussian code and $\mathrm{Q}\left({ }^{57} \mathrm{Fe}\right)=0.17$ barn. The ${ }^{57} \mathrm{Fe}$ isomer shift $\delta$ was evaluated from the DFT charge density at the Fe nucleus using the calibration given by Vrajmasu et al. ${ }^{3}$ The SCF procedure and geometry optimization were terminated upon reaching the default convergence criteria. The populations were calculated with the Population keyword.

Method 3: One calculation was performed in the same way as Method 2 but using the PBEVWN functional instead of B3LYP.

## Description of the DFT Results.

In Table S2 we present the experimental and calculated values for the magnetic hyperfine coupling constants, quadrupole splittings, and asymmetry parameters for the two iron sites in complex 2. Since, in our experience, method 2 underestimates the value of the Fermi contact term in high-valent iron species, we have only calculated the spindipolar contribution to the magnetic hyperfine parameters. The $\mathrm{A}_{\mathrm{SD}}$ values were added to $\mathrm{A}_{\mathrm{iso}}$, the average over the experimental hyperfine coupling constants, to obtain the A values listed as "calculated" in Table S2. The principal values of the EFG and A tensors have been assigned to the axes in Figures S8 and S9 (see below for discussion of axes).

Table S2. Experimental and DFT-calculated Mössbauer parameters for the $\mathrm{Fe}_{\mathrm{O}}$ and $\mathrm{Fe}_{\mathrm{OH}}$ sites of $\mathbf{2}$. ${ }^{\text {a,b }}$

Tables S3 and S4 list the total population and spin population of the individual 3d orbitals at $\mathrm{Fe}_{\mathrm{O}}$ and $\mathrm{Fe}_{\mathrm{oh}}$. The Mulliken populations have been evaluated for the SCF solution obtained with the method listed in the column labeled "prop", using the structure obtained by geometry optimization with the method indicated in the column labeled "opt".

The spin density at $\mathrm{Fe}_{\mathrm{O}}$ is consistently accommodated by the $\mathrm{d}_{\mathrm{xz}}$ and $\mathrm{d}_{\mathrm{yz}}$ orbitals. The populations of these obitals are significantly larger than 1 (Table S3) due to large covalent donation of electron density from $\mathrm{O}_{\mathrm{T}}$ into these orbitals, resulting in spin populations that are less than 1 (Table S 4 ). Orbital $\mathrm{d}_{\mathrm{xy}}$ is essentially doubly occupied, as in mononuclear $\mathrm{S}=1, \mathrm{Fe}^{\mathrm{IV}}=\mathrm{O}$ species. ${ }^{14,15}$ The results for the $\mathrm{Fe}_{\mathrm{OH}}$ site are more ambiguous. The unpaired electrons are in $\mathrm{d}_{\mathrm{xy}}$ and $\mathrm{d}_{\mathrm{xz}}$ in the optimized structure obtained with method 1 and in $\mathrm{d}_{\mathrm{xy}}$ and $\mathrm{d}_{\mathrm{yz}}$ in the optimized structure obtained with method 2. The change results from a rearrangement of the $\mathrm{t}_{2 \mathrm{~g}}$ orbitals caused by methodological differences in the dihedral angles for the core, notably in the one describing the orientation of the hydroxo group (see below).

The irons in complex 2 have mixed $4 \mathrm{~N}-2 \mathrm{O}$ coordinations, including 1 amine $\left(\mathrm{N}_{\mathrm{am}}\right)$ and 3 pyridines $\left(\mathrm{N}_{\mathrm{py}}\right)$ (1 in-plane and 2 axial pyridines) at each site, 1 bridging oxo $\left(\mathrm{O}_{\mathrm{B}}\right)$, and 1 terminal oxo $\left(\mathrm{O}_{\mathrm{T}}\right)$ at one site and a terminal hydroxo $(\mathrm{OH})$ at the other. Since $\mathrm{O}_{\mathrm{B}}$ occupies a position that is, respectively, trans to $\mathrm{N}_{\mathrm{am}}$ and $\mathrm{N}_{\mathrm{py}}$ relative to the two irons, $\mathrm{O}_{\mathrm{T}}$ must be trans to either $\mathrm{N}_{\mathrm{py}}$ or $\mathrm{N}_{\mathrm{am}}$; accordingly, OH must be trans to $\mathrm{N}_{\mathrm{am}}$ or $\mathrm{N}_{\mathrm{py}}$, respectively.
We did DFT calculations for the two isomers, $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{am}} \mathrm{FeO}_{\mathrm{B}} \mathrm{Fe}(\mathrm{OH})_{\mathrm{py}} \mathrm{L}\right]^{3+}$ and $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{py}} \mathrm{FeO}_{\mathrm{B}} \mathrm{Fe}(\mathrm{OH})_{\mathrm{am}} \mathrm{L}\right]^{3+}$ using methods 1 and 2. These calculations were performed for a complex based on the truncated ligand ( $\mathrm{L}=\mathrm{TPA}$ instead of $\mathrm{SR}_{3} \mathrm{TPA}$ ), in which the pyridine side chains were replaced by hydrogens. Tables S5 and S6 list selected distances, dihedrals, and bond angles for the two isomers obtained with the two methods. Method 2 shows that the $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{am}} \mathrm{FeO}_{\mathrm{B}} \mathrm{Fe}(\mathrm{OH})_{\mathrm{py}} \mathrm{L}\right]^{3+}$ isomer (isomer A) is lowest in energy by a margin of $436 \mathrm{~cm}^{-1}$. Most parameters show only minor variations. The most conspicuous change is in the $\mathrm{Fe}_{\mathrm{O}}-\mathrm{N}_{\text {tr }}$ distance $\left(\mathrm{N}_{\text {tr }}\right.$ is trans to $\left.\mathrm{O}_{\mathrm{T}}\right)$, suggesting a trans
effect as the origin of the energy difference between the two isomers. Interestingly, method 1 shows that the isomer $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{py}} \mathrm{FeO}_{\mathrm{B}} \mathrm{Fe}(\mathrm{OH})_{\mathrm{am}} \mathrm{L}\right]^{3+}$ (isomer B) is lowest in energy by $1000 \mathrm{~cm}^{-1}$.

Table S5. Selected distances (in $\AA$ ) for DFT optimized structures for the $\mathrm{S}=2$ states of the isomers $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{py}} \mathrm{FeOFe}(\mathrm{OH})_{\mathrm{am}} \mathrm{L}\right]^{3+}$ and $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{am}} \mathrm{FeOFe}(\mathrm{OH})_{\mathrm{py}} \mathrm{L}\right]^{3+}$ ( $\mathrm{L}=\mathrm{TPA}$ ).

${ }^{c} \mathrm{O}_{\mathrm{T}}$ is trans to pyridine and OH trans to amine.

While method 2 shows a trans effect on the $\mathrm{Fe}_{\mathrm{o}}-\mathrm{N}_{\mathrm{tr}}$ distance due to the oxo group, those distances change less between the two isomers when using method 1 . Instead, a trans effect is observed on the $\mathrm{Fe}_{\mathrm{O}}-\mathrm{O}_{\mathrm{B}}$ and $\mathrm{Fe}_{\mathrm{OH}}-\mathrm{O}_{\mathrm{B}}$ distances: the longest $\mathrm{Fe}-\mathrm{O}_{\mathrm{B}}$ distance being always the one trans to the $\mathrm{N}_{\mathrm{py}}$, the shortest being the one trans to the $\mathrm{N}_{\mathrm{am}}$. The oxo $\leftrightarrow$ hydroxo cis ligand exchange has little effect on the $\mathrm{Fe}-\mathrm{O}_{\mathrm{B}}$ distances in the optimizations with method 1. Furthermore, Table S5 shows that, regardless the isomer, the $(\mathrm{O}) \mathrm{H}---\mathrm{O}_{\mathrm{T}}$ distance is treated differently by the two methods (see below): Method 1 favors a shorter $(\mathrm{O}) \mathrm{H}---\mathrm{O}_{\mathrm{T}}$ distance $(1.427 \AA)$ compared to method $2(1.850 \AA)$. Thus, in the structure obtained with method 2 , the hydrogen atom of the OH group is closer to the
$\mathrm{O}_{\mathrm{T}}$ and the $\mathrm{Fe}_{\mathrm{OH}}-\mathrm{O}(\mathrm{H})$ is shorter than in the structure obtained with method 1. Hence, the structural dissimilarity of $\mathrm{Fe}_{\mathrm{O}}$ and $\mathrm{Fe}_{\mathrm{OH}}$ is mitigated by method 1, resulting in more balanced trans effects for the oxo and hydroxo groups and leaving the trans effect of $\mathrm{N}_{\mathrm{am}}$ and $\mathrm{N}_{\mathrm{py}}$ on the $\mathrm{Fe}-\mathrm{O}_{\mathrm{B}}$ bonds as the dominant trans effect.
From now on, we will focus on the $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{am}} \mathrm{FeOFe}(\mathrm{OH})_{\mathrm{py}} \mathrm{L}\right]^{3+}$ isomer for the following reason. We think this isomer is lowest in energy because it pairs the strongest O-donor $\left(\mathrm{O}_{\mathrm{T}}\right)$ with the weakest N -donor (amine) as trans ligand, and vice versa. (N.B. $\mathrm{Fe}_{\mathrm{O}}-\mathrm{O}_{\mathrm{T}}$ is shorter than $\mathrm{Fe}_{\mathrm{OH}^{-}} \mathrm{O}(\mathrm{H})$, regardless of the method, on the basis of which we consider $\mathrm{O}_{\mathrm{T}}$ to be stronger ligand than OH . Similarly, $\mathrm{N}_{\mathrm{py}}$ is stronger than $\mathrm{N}_{\mathrm{am}}$ since $\mathrm{Fe}-\mathrm{N}_{\mathrm{py}}$ is shorter than $\mathrm{Fe}-\mathrm{N}_{\mathrm{am}}$.) This pairing of trans ligands is supported by the crystal structure of the green intermediate $\left[\mathrm{Fe}_{2}(\mu-\mathrm{O})_{2}\left(5-\mathrm{Et}_{3}-\mathrm{TPA}\right)_{2}\right]\left[\mathrm{ClO}_{4}\right]_{3}$, which has a $\mathrm{Fe}_{2}(\mu-\mathrm{O})_{2}$ diamond core of which the shortest and longest Fe- $\mathrm{O}_{\mathrm{B}}$ distances are, respectively, trans to the $\mathrm{N}_{\mathrm{am}}$ and $\mathrm{N}_{\mathrm{py}}{ }^{16}$ The same pairing is found for the $\left[\mathrm{Fe}_{2}(\mu-\mathrm{O})_{2}\left(6-\mathrm{Me}_{3}-\mathrm{TPA}\right)_{2}\right]\left[\mathrm{ClO}_{4}\right]_{2}$ complex. ${ }^{17,18}$ We have currently not yet found a quite satisfactory explanation why method 1 calculates isomer B as the most stable isomer while method 2 prefers isomer A .

${ }^{\mathrm{a}} \mathrm{O}_{\mathrm{T}}=$ terminal oxo; am = amine; py = pyridine; $\mathrm{O}_{\mathrm{B}}=$ bridging oxo. Distances in $\AA . \mathrm{O}_{\mathrm{T}}$ is trans to amine and OH trans to pyridine.
${ }^{\mathrm{b}} \mathrm{SR}=\mathrm{SR}_{3}$ TPA
${ }^{c}$ Optimization used functional/basis (code): $1=\mathrm{BPVWN} / \mathrm{IV}(\mathrm{ADF}), 2=\mathrm{B} 3 \mathrm{LYP} / 6-311 \mathrm{G}\left(\mathrm{G}^{\prime} 03\right)$.

In Tables S 7 and S 8 we have listed selected geometrical parameters for the $\mathrm{O}_{\mathrm{T}}$-trans$\mathrm{N}_{\mathrm{am}}$ isomer, obtained for computational models with the complete ligand ( $\mathrm{L}=\mathrm{SR}_{3}$ TPA) and a truncated version of the ligand ( $\mathrm{L}=\mathrm{TPA}$ ). These tables also compare the results of method 2 with those obtained with method 1. The optimized structures have $\mathrm{X}-\mathrm{Fe}-\mathrm{Y}$ angles (not tabulated) that deviate from the ideal octahedral values $\left(90^{\circ}, 180^{\circ}\right)$ by up to $20^{\circ}$ (see, e.g., Figure S7). The two methods yield distances (Table S7) that differ by less than $0.03 \AA$, with noticeable exceptions: First, the $(\mathrm{O}) \mathrm{H} \cdots \mathrm{O}_{\mathrm{T}}$ separations differ by as
much as $\sim 0.3-0.4 \AA$, and signal a significant discrepancy between the two methods in assessing hydrogen bonding or dihedral angles. [It is presently not clear whether the methodological differences in the values for the dihedral angles defined in Table S8 (see below) are caused by the difference in hydrogen bond length, or vice versa.] Second, the $\mathrm{Fe}_{\mathrm{O}}-\mathrm{O}_{\mathrm{B}}$ and $\mathrm{Fe}_{\mathrm{OH}}-\mathrm{O}_{\mathrm{B}}$ distances as obtained with method 1 are virtually equal but differ by as much as $0.2 \AA$ in the structures optimized with method 2 .
The geometry optimizations show that complex 2 ( $\mathrm{L}=\mathrm{SR}_{3} \mathrm{TPA}$ ) and its truncated version ( $\mathrm{L}=\mathrm{TPA}$ ) are chiral molecules with non-planar $\mathrm{O}_{\mathrm{T}} \mathrm{Fe}_{\mathrm{O}} \mathrm{OFe}_{\mathrm{OH}} \mathrm{OH}$ moieties. The dihedral angles for one of the two enantiomers are listed in Table S8; the dihedrals for the second enantiomer have reversed signs. Not surprisingly, given the large discrepancy in the hydrogen bond distance, the dihedral angles obtained with the two methods are markedly different, with methods 1 and 2 resulting in moderate and large torsions angles, respectively. A comparison of the results for the full and truncated structures in Tables S7 and S 8 reveals minor differences in the distances and somewhat more substantial discrepancies in the dihedrals.

Table S8. Selected dihedral and bond angles for DFT optimized structures for the $\mathrm{S}=2$ state of $\left[\mathrm{L}\left(\mathrm{O}_{\mathrm{T}}\right)_{\mathrm{am}} \mathrm{FeOFe}(\mathrm{OH})_{\mathrm{py}} \mathrm{L}\right]^{3+}$ isomer $^{\mathrm{a}}$

The Fe-O-Fe unit is bent with an angle of $131^{\circ}$ (Table S8). To investigate the potential effect of hydrogen bonding $(\mathrm{O}) \mathrm{H} \cdots \mathrm{O}_{\mathrm{T}}$ on the $\mathrm{Fe}-\mathrm{O}-\mathrm{Fe}$ angle, we have performed a geometry optimization for a model in which the OH group was replaced by a fluoride. The substitution results in a large increase in the dihedral $\mathrm{O}_{\mathrm{T}}-\mathrm{Fe}_{\mathrm{O}}-\mathrm{Fe}_{\mathrm{F}}-\mathrm{F}$ to $143.9^{\circ}$ (using method 2 applied to the TPA complex) and a concomitant increase in the $\mathrm{Fe}-\mathrm{O}-\mathrm{Fe}$ angle to $158.6^{\circ}$, suggesting a possible influence of the hydrogen bond on the $\mathrm{Fe}-\mathrm{O}-\mathrm{Fe}$ angle of

2, although interference of other factors affected by the substitution cannot be excluded.
The latter value is slightly larger than the bridging angle in the diiron(IV) species $\left[\mathrm{B} * \mathrm{FeOFeB}{ }^{*}\right]^{2-}\left(\mathrm{Fe}-\mathrm{O}-\mathrm{Fe}=153^{\circ}\right)$, where the bending was shown to be an intrinsic property of the FeOFe unit. ${ }^{14}$

${ }^{\mathrm{f}} \mathrm{A}$-values are listed here in increasing order of their values.

Table S9 lists hyperfine parameters obtained with different methods and for both the complete (SR) and truncated ligand system (TPA). With a few exceptions, the eigenvalues of the EFG and $\mathrm{A}_{\mathrm{SD}}$ tensors come out relatively constantly. The $\Delta \mathrm{E}_{\mathrm{Q}}$ values for $\mathrm{Fe}_{\mathrm{O}}$ are consistently smaller than those for $\mathrm{Fe}_{\mathrm{OH}}$, irrespective of method or ligand truncation, in accordance with experiment. The values for $\Delta \mathrm{E}_{\mathrm{Q}}$, predicted using $\mathrm{Q}\left({ }^{57} \mathrm{Fe}\right)=$ 0.17 barn, are systematically somewhat higher than those observed experimentally. [To accommodate this observation we proposed in ref. ${ }^{19}$ the use of a slightly smaller value of $\mathrm{Q}\left({ }^{57} \mathrm{Fe}\right)$ for predicting the quadrupole splitting in high-valent iron complexes with method 2.] The calculated values for $\eta$ vary over a broad range and appear to be hard to predict for this system. The calculated $\mathrm{A}_{\mathrm{SD}}$ values for $\mathrm{Fe}_{\mathrm{O}}$ are nearly axial, while those for $\mathrm{Fe}_{\mathrm{OH}}$ show a significant degree of rhombicity, in accord with the Mössbauer analysis (Table S9). As expected, methods 1 and 3 yield similar quadrupole splittings for the structure optimized with method 1 .

Figure S11. DFT-calculated spin density for 2. $\mathrm{Fe}_{\mathrm{O}}$ is on the left. The geometry has been optimized with method 1 , and the spin density has been calculated with method 2 .

As can be seen from the spin-density profile in Figure $S 11$ (for SR $_{3} T P A$ ) the $t_{2 g}$ orbitals of $\mathrm{Fe}_{\mathrm{OH}}$ are engaged in $\pi$ interactions with the lone-pair p-orbitals at the hydroxide
oxygen and the bridging oxygen. As a result, the torsion angle of the hydroxide ligand has an important effect on the composition of the $\mathrm{t}_{2 \mathrm{~g}}$ orbitals (and their energies) and related properties such as the EFG, $\mathrm{A}_{\mathrm{SD}}$, and J. Probably to a lesser degree, these properties may also be affected by the $(\mathrm{H}) \mathrm{O}-\mathrm{Fe}_{\mathrm{OH}}-\mathrm{Fe}_{\mathrm{O}}-\mathrm{O}_{\mathrm{T}}$ torsion. Since the torsion angles are dependent on the method used for the optimization, the properties should exhibit methodological differences as well. Particularly affected are the orientations of the principal axes of the EFG and $\mathrm{A}_{\mathrm{SD}}$ tensors for $\mathrm{Fe}_{\mathrm{OH}}$ (not listed). In the case of small torsions, such as in the optimized structures obtained with method 1 , the principal axes on $\mathrm{Fe}_{\mathrm{OH}}$ site are expected to be roughly collinear with the metal-ligand bonds with the largest component of the two tensors being along x , whereas in the case of large torsions, as obtained with method 2, the ligand and tensor frames are far from collinear. [In fact, the structure optimized with method 1 gives already rise to a considerable degree of noncollinearity between the ligand and tensor frames at $\mathrm{Fe}_{\mathrm{OH}}$, see main text.] In contrast, the dihedrals in Table $S 8$ have little effect on the orientation of the principal axes of the tensors for $\mathrm{Fe}_{\mathrm{O}}$, where the z axis is invariably along the $\mathrm{Fe}_{\mathrm{O}}-\mathrm{O}_{\mathrm{T}}$ vector. Unlike the spin density in the $\mathrm{d}_{\mathrm{x}^{\prime} \mathrm{y}^{\prime}}$ orbital at $\mathrm{Fe}_{\mathrm{OH}}$, the spin density in the $\mathrm{d}_{\mathrm{yz}}$ orbital at $\mathrm{Fe}_{\mathrm{O}}$ exhibits only minor spin delocalization toward the oxo bridge, possibly because of $\mathrm{sp}^{2}$ hybridization at $\mathrm{O}_{\mathrm{B}}$ in the yz plane.
