| Experiment ${ }^{\text {b }}$ | 0.357 | 0.414 | 1.16 | c | c | $<1.26{ }^{\text {c }}$ |

${ }^{\text {a }}$ From G2MP2 calculation of bis-allylic C-H BDE; $77.3 \mathrm{kcal} / \mathrm{mol}$ for 1,4 -pentadiene and $76.8 \mathrm{kcal} / \mathrm{mol}$ for Z,Z-2,5heptadiene. ${ }^{\mathrm{b}}$ Spin densities obtained from the experimentally determined $\alpha$-hfcc s. ${ }^{\mathrm{c}}$ Not determined, but $S_{\mathrm{C} 2, \mathrm{C} 6}=$ $0.352, S_{\mathrm{C} 4}=0.425$ yielding $S_{\mathrm{C} 4} / S_{\mathrm{C} 2, \mathrm{C} 6}=1.21$ in $E-2,5$-hexadien- 4 -yl allows us to estimate a value of $<1.26$.

The ( $E, E$ )-1,4-pentadien-3-yl radical has a minimum energy structure of $\mathrm{C}_{2} \mathrm{v}$ symmetry and has a ${ }^{2} \mathrm{~B}_{1}$ electronic state. It is interesting to note that when studying the $Z, Z-(E, E)-2,5-$ heptadien-4-yl radical, when the geometry is forced to be of $\mathrm{C}_{2} \mathrm{v}$ symmetry (and the corresponding ${ }^{2} \mathrm{~B}_{1}$ state), there is an imaginary vibrational mode corresponding to low barrier rotations of the terminal methyl groups. Breaking symmetry (giving a $\mathrm{C}_{1}$ structure) and optimizing the geometry of the radical with tighter convergence criteria leads to a structure with all positive vibrational modes, and an electronic energy of - $0.3 \mathrm{kcal} / \mathrm{mol}$ by UHF/6-31G(d), and -0.9 by ROB3LYP/6-311G(2d, 2 p ) at the HF minimum energy geometry.

The autoxidation of 1,4-cyclohexadiene yields products consistent with $40 \%$ of oxygen addition to form a bis-allylic peroxyl radical, whereas $60 \%$ of oxygen addition occurs at either of the terminal positions of the pentadienyl system in the cyclohexadienyl radical. ${ }^{1}$ This translates to a 1:1.33:1 relative spin distribution on the first, third and fifth carbon of the radical. Interestingly, theoretical calculations (B3LYP/6-31G*) yield the same spin density distribution in the $\mathrm{C}_{2} \mathrm{v}\left({ }^{2} \mathrm{~B}_{1}\right)$ cyclohexadienyl radical (1:1.32:1). ${ }^{2}$

It is of interest to note that spin densities predicted by theory (Table 1) do not accurately reflect the product ratios seen in the competition experiments described here, i.e., 1:1.08:1 (B3LYP/6-31G*) versus 1:1.45-1.51:1 (experiment). The ratios of the spin densities are in reasonable agreement with experimental ESR measurements (which also predict a lower relative amount of addition at the central carbon atom), and there is good agreement between the G2MP2-calculated central C-H BDE in the pentadienylic systems and experimental values. We also note that theory predicts more spin on the central carbon atom of the cyclohexadienyl radical relative to that in the acyclic pentadienyl radical.

[^0]The difference in rates of $\beta$-fragmentation of the 9/13-peroxyl and the 11-peroxyl are best understood in terms of the calculated ${ }^{3} \mathrm{C}-\mathrm{OO} \bullet$ bond dissociation enthalpy (BDE) of each of the two peroxyl radicals. The terminal peroxyls $(9 / 13)$ have a much stronger C-OO• BDE (9.9 $\mathrm{kcal} / \mathrm{mol}$ ), leading to a lower rate of $\beta$-fragmentation ( $430 \mathrm{~s}^{-1}$ ), whereas the bis-allylic peroxyl (11) has a much weaker $\mathrm{C}-\mathrm{OO} \bullet \mathrm{BDE}(\mathbf{3 . 6} \mathrm{kcal} / \mathrm{mol})$, leading to a much higher rate of $\beta$ fragmentation ( $1.9 \times 10^{6} \mathrm{~s}^{-1}$ ). The difference in the calculated BDE s $(6.3 \mathrm{kcal} / \mathrm{mol})$ compare very well with experiment, as the ratio of the rate constants allow us to derive $\Delta E_{a}=6.6 \mathrm{kcal} / \mathrm{mol}$ from the ratios of the Arrhenius functions, assuming an A-factor of $1 \log$ unit larger in the case of the dissociation of the bis-allylic peroxyl since an extra rotation must become frozen in the transition state for C-OO• dissociation.

## Determination of $\boldsymbol{k}_{\text {inh }}$

At low concentrations of any inhibitor, Eq. 1 reduces to Eq. 2, for which $\alpha$ and $k \beta$ have been determined. Thus, $\alpha=0.43-0.02$ and $k_{\beta}=1.9(-0.2) \times 10^{6} \mathrm{~s}^{-1}$.

$$
\frac{[4]}{[3+5]}=\frac{k_{\text {inh }}[\text { Inhibitor }]}{k_{\beta}} \cdot \frac{\alpha}{1-\alpha} \quad \text { Eq. } 2
$$

Plotting $[4] /[3+5]$ vs. inhibitor concentration gives a line with slope defined by Eq. 2, the only unknown being $\boldsymbol{k}_{\text {inh }}$.

## HPLC Standardization

Figure S1. HPLC standardization. Detection at 207 nm , NMR standardized by integration of 1 vinylic hydrogen from 3 and 5 (dd, 6.5§) and two vinylic hydrogens from 4 (t, 5.35 ).
