## Bond valence sum (BVS) analysis

Bond valence sum (BVS) analysis was used to identify the central anion as hydroxo or oxo as well as the oxidation states of metal ions. The valence of a bond between two atoms, $i$ and $j$ is given by $S_{i j}$. The BVS for a given metal ion is the sum of bond valences for each bond made to that metal ion. The $r_{0}$ values are determined empirically such that the BVS is generally quite close to the oxidation state of the metal ion. In this work, $i$ and $j$ are $\mathrm{Ni}, \mathrm{O}$ for compound $\mathbf{1}$ or $\mathrm{Co}, \mathrm{O}$ for compound 2. The charge $V i$ on one Nil or Col in the trinuclear $\mathrm{M}_{3}$ unit is the sum of $S_{i j}$ calculated from all six bonds connected to it, $i e$; the valence of the $i$ atom. (See SI of Chem. Commun. 2007, 840-842). B is a constant, the "universal parameter" $\sim 0.37 \AA$. The
calculated results are shown in the following tables, which are closed to the literature result.

## The PXRD Patterns

Figure S6. PXRD patterns of simulated from the X-ray single-crystal structures and
as-synthesized samples of 1 (a) and 2 (b) at ambient temperature.

The powder X-ray diffraction (PXRD) experiments for $\mathbf{1}$ and 2 were carried out carefully to check phase purity at room temperature. The patterns showed that the main peaks of the synthesized MOFs were closely consistent with those of the simulations from the single-crystal X-ray diffraction data, which imply high quality of the obtained products.
